Another study evaluated 33 non-lymphoma haematological cancers, including 13 classified as of lymphoid lineage (multiple myeloma in five, plasmacytoma in three, B cell chronic lymphocytic leukaemia in three, precursor cell lymphoblastic leukaemia and unspecified lymphoid leukaemia in one case each, respectively), and 20 cases as of myeloid lineage (myelodysplastic syndrome in seven, acute myeloid leukaemia in seven, chronic myeloid leukaemia in two and four unspecified leukaemias). In this large SLE cohort, the most common non-lymphoma haematological malignancies were myeloid types, and the majority (80%) of multiple myeloma cases occurred in blacks. This is in contrast to the general population, where lymphoid types are 1.7 times more common than myeloid non-lymphoma haematological malignancies (Lu et al, 2013).

9.3 Disease activity is the main risk factor of lymphoma in RA but not in SLE

Large Swedish studies have compared, using the national registry of RA, 378 patients with RA and lymphoma with 378 age- and sex-matched controls (patients with RA without lymphoma) (Baecklund et al, 2014). There was a slight mismatch between the two groups for the disease duration, which was longer in patients with lymphoma than in controls (20 vs 17 years). All histological slides were reassessed and investigated for the presence of EBV. EBV was detected in 12% of all lymphomas, and in 47% of HL. The authors established a global disease activity score and a cumulative disease activity score during the 20 years preceding lymphoma. This cumulative score was then divided into 10 deciles of activity, each decile including the same number of patients.

The risk of lymphoma is not much increased until the end of the seventh decile. This risk increases by 9.4 (95% CI 3.1 to 28) in patients in the ninth and by 61.6 in patients of the 10th decile, which includes the 10% of patients in whom disease activity was the highest.

This study also allowed an evaluation of the role of treatments. All patients were included before 1995, and none had received TNF blockers. Overall, use of disease-modifying antirheumatic drugs was not associated with an increased risk of lymphoma. However, AZA administration was associated with lymphoma development (OR = 2.3, 95% CI 1.2 to 4.6).

In contrast, a case-control study by Bernatski et al (2014), including 75 patients with lymphoma and 4961 cancer-free controls, found that unadjusted and adjusted analyses failed to show a clear association between SLE disease activity and lymphoma risk.

9.4 Methotrexate is not associated with an increased risk of NHL

Some EBV-associated lymphomas have been reported in patients with RA, one-third being regressive after the discontinuation of MTX, but the long-term evolution of the disease in these patients is rarely reported. These often-aggressive lymphomas share similarities with lymphomas occurring in immunosuppressed patients (after allogeneic bone marrow transplantation, organ transplantation, in late stages of AIDS).

Interestingly, MTX was not associated with an increased risk of lymphoma in Swedish studies (Baecklund et al, 2014). This result is concordant with the previous results of six long-term follow-up studies of patients with RA. For instance, a French prospective study collected 25 lymphomas during a 3-year follow-up, including 18 NHL and 7 HL. The HL was severe (four deaths) and often associated with EBV (five out of seven patients). The incidence of NHL in the patients with RA was not higher than that in the general French population, after adjustment for age and sex. However, the incidence of HL was increased (Mariette et al, 2002).

9.5 Controversial association between anti-TNF agents and lymphoma

Several studies have provided insight into this complex problem.

9.5.1 Data from the 'National Data Bank of Rheumatic Diseases'

Wolfe coordinated the follow-up of around 20 000 patients with RA (Wolfe et al, 2004). Twenty-nine lymphomas have been reported in 18 572 patients with RA since 1998. The SIR of lymphomas in RA was estimated to be 1.9. The SIR of patients treated with MTX (1.7) was not significantly different from that of the general population, and the SIR was 2.9 in patients with anti-TNF (table 8).

Similar SIRs were obtained in controlled trials with adalimumab: 15 lymphomas in 9460 patients, which corresponds to 9894 patients/year, with a SIR of 3.19 (95% CI 1.78 to 5.26), non-significantly different from the SIR of infliximab or etanercept.

Table 8 Incidence of lymphomas in RA according to the data from the National Data Bank of Rheumatic Diseases

	Standardised incidence rate (SIR)	
	SIR	95% CI
General population	1.0	
All patients with RA	1.9	1.3 to 2.7
No biological agents or MTX	1.0	0.4 to 2.5
MTX	1.7	0.9 to 3.2
Infliximab	2.6	1.4 to 5.0
Etanercept	3.8	1.9 to 7.5
All biological agents	2.9	1.7 to 4.9

9.5.2 Data from the national Swedish registry

This registry which, as previously mentioned, included about 70% of all patients with RA in Sweden, compared three cohorts: one prevalent including inpatients between 1990 and 2003 (n = 53 067), one incident including patients diagnosed with RA between 1995 and 2003 (n = 3703) and one cohort of patients treated with anti-TNF (etanercept, infliximab and adalimumab) (Askling et al, 2005).

These three cohorts were compared with the general population after referring to the Swedish registry of cancer to evaluate the risk of haematological malignancy. The SIRs (95% CI) of lymphomas in the prevalent, incident and exposed to anti-TNF cohorts were 1.9 (1.7 to 2.1), 2.0 (1.0 to 3.5), and 2.9 (1.3 to 5.5), respectively (table 9). No increased risk due to anti-TNF exposure was found after adjustment for sex, age and disease duration. Thus, to interpret the marginal increase of the risk of lymphoma in patients treated with anti-TNF, one should take into account the fact that such patients have an important inflammatory activity.

Table 9 Data on lymphoma from the national Swedish registry

	Prevalent RA n = 53067		Incident RA n = 3703		RA exposed to anti-TNF n = 4160	
	N	SIR* (95% CI)	N	SIR* (95% CI)	N	SIR* (95% CI)
Lymphomas (including CLL)	319	1.9 (1.7 to 2.1)	11	2.0 (1.0 to 3.5)	9	2.9 (1.3 to 5.5)

*Adjusted results. CLL, chronic lymphocytic leukaemia; RA, rheumatoid arthritis; SIR, standardised incidence rate.

9.5.3 Data from a French registry

According to the results from recent French studies (Mariette et al, 2010; Mariette et al, 2011), the incidence of lymphoma was found to be increased among patients with RA treated with (infliximab/adalimumab) compared with soluble-receptor anti-TNF (etanercept), with corresponding SIR (95% CI) of 4.1 (2.3 to 7.1) or 3.6 (2.3 to 5.6) vs 0.9 (0.4 to 1.8).

9.5.4 Review of T cell NHL reported to the FDA in patients receiving TNF α inhibitors

A recent study (Deepak et al, 2013) has evaluated a total of 3 130 267 reports downloaded from the FDA Adverse Event Reporting System (AERS) (2003–2010). Ninety-one cases of T cell NHL related to TNF α inhibitors were identified in the FDA AERS and nine additional cases were identified on Medline search. A total of 38 patients had RA, 36 had Crohn's disease, 11 had psoriasis, nine had ulcerative colitis and six had ankylosing spondylitis. Sixty-eight of the cases (68%) involved exposure to both a TNF α inhibitor and an immunomodulator (AZA, 6-mercaptopurine, MTX, leflunomide, or CsA). Hepatosplenic T cell lymphoma was the most commonly reported subtype. The authors concluded that the risk of T cell NHL is increased by the use of a TNF α inhibitor in combination with thiopurines, but not by use of TNF α inhibitors alone.

9.5.5 Lymphoma and anti-TNF agents: summary

Recent data suggest a possible increase of the incidence of lymphoma in patients treated with anti-TNF (Wong et al, 2012). However, the interpretation of this increase is complex since disease activity is a major risk factor for lymphoma, and the more active the RA, the more likely are patients to receive anti-TNF agents. Thus, a recent meta-analysis of the risk of lymphoma from RA registries concluded that the risk of lymphoma with anti-TNF agents was the same as the risk of lymphoma with other classic disease-modifying antirheumatic drugs (Mariette et al, 2011).

Thus, it is impossible to know whether this increased risk of lymphoma is related to anti-TNF agents or to increased disease activity of the patients treated with biological agents. If the latter hypothesis is correct, the risk related to increased disease activity should be rapidly corrected by clinical improvement allowed by anti-TNF. The question remains...

SUMMARY POINTS

- Sjögren's syndrome (SS) is a multi systemic autoimmune disease that mainly affects the exocrine glands, with a clinical spectrum that extends to systemic involvement (extra glandular manifestations).
- The disease can appear in many guises depending on specific epidemiological, clinical or immunological features, although it overwhelmingly affects middle-aged women.
- It may be a serious disease with excess mortality, mainly related to systemic involvement and haematological cancer., but also it can be a disease with very little objective signs but with burden of the patient because a poor quality of life
- The proven diagnosis of SS requires documentation of sicca symptoms, objective evidence of dry eyes and mouth analytical evidence of autoimmunity, as sicca syndrome has many causes and a lip biopsy specially in serological negative patients.
- The therapeutic management of SS should have a multisystemic approach taking in account a clear and comprehensive teaching of the patient about his illness and understanding the poor quality of life patients normally experience.
- It mainly centres on the control of sicca features, using substitutive and oral muscarinic agents, while glucocorticoids, immunosuppressive and biological agents play a key role in the treatment of extra glandular features.
- Primary SS is the autoimmune disease in which the risk of lymphoma is the highest. An increased risk of B cell lymphoma has also been reported in other rheumatic and autoimmune diseases.
- Chronic immune stimulation, genetic and environmental factors and some immunosuppressive/biological drugs might be involved in lymphomagenesis in autoimmune diseases other than SS.

Sjögren's syndrome and lymphoproliferations in autoimmune diseases

Cristina Vollenweider, Margarita Landi, Manuel Ramos-Casals

A previous version was coauthored by Pilar Brito-Zerón, Manuel Ramos-Casals, Athanasios G. Tzioufas

IN-DEPTH DISCUSSION I

**Primary and associated Sjögren's syndrome:
Role of autoantibodies**

Patients with primary Sjögren syndrome (SS) sometimes demonstrate autoantibodies considered characteristic of other systemic autoimmune diseases (SAD). In such cases, the clinical significance of this immunological overlap (if any) has not been established. Some studies have attributed the presence of certain autoantibodies merely to the B-cell hyperactivity that is characteristic of primary SS. In contrast, other studies have implied that the presence of such autoantibodies signals a predictive role and a greater likelihood for the emergence of an additional associated SAD. Indeed, a significant clinical and immunological overlap between SS and other autoimmune diseases may exist (Table 1).

Table 1. Clinical and immunological overlap between primary SS and other systemic autoimmune diseases

Systemic autoimmune diseases	OVERLAP FEATURES	
	Clinical	Immunological
Systemic lupus erythematosus	Arthritis Leukopenia Thrombocytopenia SCLE	ANA Anti-DNA Hypocomplementaemia
Rheumatoid arthritis	Arthritis	RF
Systemic sclerosis	Raynaud phenomenon Pulmonary fibrosis	ACA
Mixed connective tissue disease	Puffy hands Raynaud phenomenon Myositis Synovitis	Anti-RNP
Sarcoidosis	Parotid enlargement Erythema nodosum	-
Systemic vasculitides	MVV Livedo reticularis Purpura Neuropathy	Cryoglobulins ANCA
Antiphospholipid syndrome	Thrombocytopenia Livedo reticularis	aPL

SCLE: sub-acute cutaneous lupus erythematosus; ACA anticentromere antibodies; MVV: medium-vessel vasculitis; aPL: antiphospholipid antibodies.

I. ANTIMITOCHONDRIAL ANTIBODIES

There is a small subset of patients with primary SS and positive anti-mitochondrial antibodies (AMA) (8%), an immunological marker closely related to primary biliary cirrhosis (PBC). However, 50% of SS patients who have AMA demonstrate clinical or laboratory test evidence of liver disease (Ramos-Casals et al, 2008). Liver biopsy reveals usually a stage I PBC (Hatzis et al 2008). This suggests the existence of an incipient or incomplete PBC in some patients with primary SS, progressing very rarely to end-organ damage.

II. ANTI-dsDNA ANTIBODIES

Few studies have analysed the clinical significance of anti-dsDNA antibodies in patients with primary SS. In a study of 26 patients with primary SS patients who had anti-dsDNA autoantibodies (Ramos-Casals et al, 2006), features of systemic lupus erythematosus (SLE) included ANA positivity in all cases, leukopenia in 14 (54%) and articular involvement in 9 (35%). Other SLE features, such as skin, renal and central nervous system involvement were uncommon. After a median follow-up of nearly 6 years, 8 (31%) of the 26 SS patients with anti-dsDNA antibodies at baseline fulfilled 4 or more of the classification criteria for SLE and 10 (38%) fulfilled 3 criteria.

In another study, Manoussakis et al (2004) described the clinical characteristics of 26 patients with coexistence of SS and SLE. Autoantibodies were not useful in distinguishing between SLE and SS-SLE patients and the clinical presentations of the two patient groups were similar. Therefore, there is a substantial overlap in the clinical and serologic features of primary SS and SLE, and the consequent difficulties in using classification criteria to distinguish between them has been emphasized (Isenberg et al, 2004).

III. ANTI-Sm ANTIBODIES

Anti-Sm antibodies are rarely found in patients with primary SS (Ramos-Casals et al, 2006). A close follow-up of primary SS patients with positive anti-Sm antibodies is suggested, in order to detect clinical and/or analytical data suggesting the development of an additional SAD, and thus, an evolution from a single autoimmune disease (primary SS) to an overlap syndrome (generally, SS associated with SLE).

IV. ANTI-RNP ANTIBODIES

Some patients with primary SS have positive anti-RNP antibodies. Several studies have analysed anti-RNP antibodies in small series including patients with primary and associated SS and found a prevalence ranging between 4% and 28% (Ramos-Casals et al, 2006). Overlap syndromes between SS and mixed connective tissue disease occurs in some patients.

V. ANTIPHOSPHOLIPID ANTIBODIES

Antiphospholipid antibodies (aPL) are the most frequently detected atypical autoantibodies in primary SS (Table 2) (Ramos-Casals et al, 2006). In spite of the frequency in which aPL are detected, the fully-expressed antiphospholipid syndrome (APS) occurs in only a minority of primary SS patients. In a meta-analysis by Ramos-Casals et al, 2006, only 12 (9%) of 134 SS-aPL patients fulfilled the 1999 APS classification criteria. The coexistence of primary SS and APS should be considered an infrequent (but not exceptional) event that occurs in approximately 10% of primary SS patients who have aPL. Routine aPL determination in patients with

primary SS is not recommended except in those with specific clinical (thrombosis or repeated miscarriages) or analytical (thrombocytopenia, haemolytic anaemia) features consistent with APS (Ramos-Casals et al, 2007).

Table 2. Prevalence of atypical immunological markers in patients with primary SS (Ramos-Casals et al, 2006)

Atypical antibodies	Patients with primary SS (positive/tested)	Prevalence
aPL	120/589	20.4%
ANCA	43/357	12%
ACA	11/137	8%
Anti-CCP	11/166	6.6%
Anti-dsDNA	34/718	4.7%
Anti-RNP	34/782	4.3%
Anti-Scl70	2/92	2.2%
Anti-Sm	8/457	1.7%

VI. ANTI-Scl70 ANTIBODIES

No studies have analysed the prevalence and clinical significance of these autoantibodies in patients with primary SS, with only two isolated cases being reported in patients with coexisting SS and SLE (Al Attia et al, 2003) and 2 cases with primary SS and anti-Scl70 (anti-topoisomerase I) antibodies. None of these 4 patients presented clinical features suggestive of systemic sclerosis (SSc). However, Fauchais AL et al (2010) described 3 SS patients with Scl70 antibodies, 2 of whom developed SSc. Therefore, clinicians should be aware of the possibility of the development of scleroderma features in patients who have these autoantibodies.

VII. ANTICENTROMERE ANTIBODIES

In contrast to anti-Scl70 antibodies, anticentromere antibodies (ACA) seem to have a higher prevalence and greater clinical significance in patients with primary SS, with nearly 100 cases being reported (Ramos-Casals et al, 2006) (Salliot et al, 2007) and a prevalence ranging from 4-8% in large series of primary SS patients (Bournia et al, 2010) (Baldini et al, 2013) (Ramos-Casals et al, 2006).

Although, SS patients with ACA antibodies seem to have little tendency to evolve to a full-blown systemic sclerosis (Bournia et al, 2010) (Baldini et al, 2013), routine testing for ACA in patients with primary SS is recommended for those who have Raynaud's phenomenon, and especially in patients with high titers of ANA but negative anti-Ro/La antibodies. Close physical examination for incipient cutaneous changes that suggest limited systemic sclerosis, particularly a nailfold capillaroscopic analysis, is essential. In addition, SS-ACA

patients should be monitored closely for the development of gastrointestinal or pulmonary manifestations that may commonly complicate systemic sclerosis.

A recent study (Baer et al. 2016) from the SICCA cohort including over 1300 patients described a subset of pSS patients with positive ACA. ACA was associated with older age, female sex, and lower frequency of anti-SSA/SSB, rheumatoid factor and hyperglobulinemia. ACA-SS patients were more likely to have a worse exocrine glandular dysfunction and a higher focus score in salivary gland biopsy; however, ACA was not associated with glandular fibrosis.

VIII. ANTI-NEUTROPHIL CYTOPLASMIC ANTIBODIES (ANCA)

A total of 59 patients with primary SS and positive ANCA have been reported (Ramos-Casals et al, 2006). The potential clinical significance of these autoantibodies in patients with primary SS is defined by three points: the prevalence of the different immunofluorescence patterns and enzyme immunoassay specificities; the association of these autoantibodies with specific extra glandular features of SS; and the overlap with systemic vasculitis.

The clinical significance of ANCA in patients with primary SS can be summarized by an overwhelming prevalence of the p-ANCA pattern, although antibodies directed against myeloperoxidase are found in less than 20% of cases. Thus, there appears to be little utility in the routine determination of ANCA in patients with primary SS. ANCA testing should be reserved for those in whom a high index of suspicion for a true “pauci-immune” form of systemic vasculitis exists.

IX. ANTI-CITRULLINATED ANTIBODIES

Arthritis in primary SS has been predominantly reported in the proximal interphalangeal (35%) and metacarpophalangeal joints (35%), and wrists (30%). Radiologically, SS-related arthritis is overwhelmingly classified as non-erosive, with bone erosions being found in only 4% of patients. The main autoimmune disease that should be discarded in the presence of anti-CCP is rheumatoid arthritis (RA). The high frequency of rheumatoid factor (RF) in primary SS means this marker is not suitable for the differentiation of RA and SS, but anti-CCP antibodies may be more useful. Seventeen studies have tested anti-CCP in patients with primary SS and found positivity in only 7% of cases (Table 3).

Table 3. Prevalence of anti-CCP antibodies positivity in patients with primary SS

Author	Year	Primary SS patients (n)	Anti-CCP+ (%)	Characteristics of joint involvement in CCP+ patients (n)
Dubucquoi et al	2004	47	2 (4%)	Not detailed
Gottenberg et al	2005	134	10 (7%)	Arthritis (2)
Kamali et al	2005	35	1 (3%)	Not detailed
Sauerland et al	2005	30	1 (3%)	Not detailed
Tobon et al	2005	53	5 (10%)	Arthritis (2), arthralgias (2), no X-ray erosions
Van noord et al	2005	108	3 (3%)	Arthritis (1)
Haga et al	2007	102	5 (5%)	Arthritis (1)
Atzeni et al	2008	155	14 (9%)	Arthritis (12)
Bodil et al	2008	78	4 (5%)	Arthritis (3)
Barcelos et al	2009	31	2 (6%)	Arthritis (0)
Iwamoto et al	2009	73	3 (4%)	Joint involvement (3), no X-ray erosions

Kim et al	2012	95	21 (22%)	Arthralgia (20), arthritis (16)
Ryu et al	2012	405	38 (9%)	Arthralgia (32), arthritis (28)
TOTAL		1907	118 (7%)	

X. MUSCARINIC TYPE 3 RECEPTOR AUTOANTIBODIES

Anti-muscarinic type 3 receptor autoantibodies (anti-M3R) are potential inhibitors of saliva secretion in SS. Extensive efforts have shown that anti-M3R are positively associated with focus score and negatively associated with saliva flow rate. Although there is not yet a test commercially available to detect them, studies supporting their inclusion as a non-invasive serologic marker for the diagnosis of SS exist. (Zuo et al. 2016)

XI. NOVEL ANTIBODIES

Recent studies have identified new autoantibodies; these are anti-salivary gland protein-1 (SPS 1), anti-carbonic anhydrase 6 (CA6) and anti-parotid secretory protein (PSP). A recent study has identified these antibodies in 60% of patients suffering from dry eye. Only 30% of the patients with one of these autoantibodies had longstanding SS. Therefore, testing for these novel autoantibodies may allow an earlier recognition of SS. (Everett S, et al 2017)

CONCLUSION

In conclusion, a great heterogeneity in the immunological presentation of primary SS is often observed, including the presence of multiple autoantibodies against both nuclear and non-nuclear antigens. ANA play a central role in the immunological expression of primary SS because of their frequency, their association with clinical SS features and their close association with autoantibodies directed against ENA. Anti-Ro/SSA and anti-La/SSB antibodies are closely related to the extra glandular expression of primary SS and identify the most clinically and immunologically “active” subset of primary SS patients. The presence of some antibodies directed against non-nuclear antigens, e.g., anti-mitochondrial antibodies, suggests an association between primary SS and other organ-specific autoimmune diseases, especially primary biliary cirrhosis. For other antibodies directed against non-nuclear antigens, e.g., parietal cell antibodies and smooth muscle antibodies, the associations are less clear or even believed to be of little or no clinical significance.

Testing for atypical autoantibodies mainly anti-dsDNA, aPL, anti-centromere, ANCA, anti-CCP may be helpful in diagnosing a possible overlap between primary SS and other SAD. Although patients with atypical autoantibodies are often classified initially as having primary SS (most of them also fulfilling the 2002 classification criteria for SS), 20% may fulfil classification criteria for an additional SAD during follow-up. The risk of developing an additional SAD differs according to the atypical autoantibody present at the diagnosis of “primary” SS. Patients having anti-dsDNA or anti-centromere antibodies are at higher risk of developing an additional disease and require closer follow-up in order to detect clinical and/or analytical data suggestive of coexisting SLE or systemic sclerosis.

IN-DEPTH DISCUSSION II

IgG4-related disease

IgG4-related disease (IgG4-RD) is a systemic immune-mediated disease described in Japan in the first years of the 21st century and is characterized by tissue infiltration of IgG4-bearing plasma cells (Stone et al, 2012). It is not a new disease, because many previously-recognised conditions of an unknown aetiology and pathogenesis, formerly regarded as entirely disparate disorders, are now known to comprise parts of the IgG4-RD spectrum. Such conditions include Mikulicz disease, Küttner's tumour, Riedel thyroiditis, and Ormond disease, among others (Kamisawa et al, 2015).

The cardinal feature of IgG4-RD is single or multiple organ swelling. IgG4-RD usually presents sub acutely and most patients are not severely or acutely ill. The disease may be diagnosed incidentally through radiological findings or unexpectedly in pathological specimens, especially in single organ presentations. Multi-organ disease is easier to identify at diagnosis but may evolve metachronously over months to years. Involvement of major organs is common and may lead to organ failure, particularly in the pancreas, liver and biliary tree, kidneys, thyroid gland, lungs, and aorta. Signs and symptoms at presentation are diverse and may be divided into general and organ-specific. Most reports have focused on describing the organs involved and not on the signs and symptoms that led ultimately to the diagnosis (Brito-Zerón et al, 2015).

It is important to note that the presenting features vary substantially according to the specialty to which the patient presents first (Table 1). Gastroenterologists are more likely to encounter patients with jaundice, pruritus and mild abdominal discomfort resulting from autoimmune pancreatitis or IgG4-related sclerosing cholangitis. Rheumatologists, in contrast, are more likely to encounter patients with major salivary gland enlargement because this disease feature often raises the spectre of Sjögren's syndrome. Ophthalmologists are more likely to be referred patients with lachrymal gland swelling or other orbital lesions; nephrologists to evaluate patients with renal dysfunction caused by tubulointerstitial nephritis; and so forth.

Major salivary glands are one of the organs more frequently involved in the IgG4-related disease, reported in 40% of cases (40%). IgG4-related glandular involvement has been specifically studied in several studies including patients with Mikulicz disease (defined as the bilateral swelling of at least two major salivary or lachrymal glands) and Kuttner disease (also known as chronic sclerosing sialadenitis, affecting submandibular glands). Glandular swelling, often subacute, is the key sign on examination: submandibular glands are affected in more than 90% of patients, parotid glands in 30% and sublingual glands in less than 10 cases (Moriyama et al, 2012). Bilateral involvement is more frequent in systemic than in localized IgG4-RD. A recent study has reported that all affected glands showed well-defined borders, with two types of sonographic appearance (localized tumour-forming and diffuse focal involvement) (Asai et al, 2013). In patients with IgG4-related glandular disease, sicca symptoms have been reported in two thirds of patients.

Four main laboratory abnormalities (eosinophilia, hypergammaglobulinaemia, elevated serum IgE levels, and hypocomplementaemia) may lead to suspicion of IgG4-RD. Raised serum IgG4 levels were the key feature in

identifying the first cases of IgG4-RD, although recent studies have reported some significant limitations of serum IgG4 measurement (Carruthers et al, 2014). Histopathological studies showing specific histological features (storiform fibrosis, eosinophilic infiltration and obliterative phlebitis) and IgG4 tissue immunostaining are the most reliable diagnostic tools, although they are not pathognomonic and may show significant variations according to the organ biopsied, the time of disease evolution or the therapies administered. Recent studies have suggested a potential role of flow cytometry studies in the diagnosis and longitudinal management of IgG4-RD.

IgG4-RD should be suspected in patients presenting with unexplained enlargement or swelling of one or more organs (Stone et al, 2012). General symptoms such as asthenia or weight loss (especially reported by patients with intra-abdominal involvement) are common but usually subacute and therefore difficult to recognise. Fever occurs in only a small minority of patients, even those with impressive degrees of weight loss. The diagnosis of IgG4-RD relies on the coexistence of various clinical, laboratory and histopathological findings, although none are pathognomonic alone (Deshpande et al, 2012). Nevertheless, demonstration of the classic histopathologic proof of the diagnosis is crucial in most cases and strongly preferred before the initiation of treatment.

The diagnostic approach is heterogeneous, and the first proposed sets of criteria centred on a specific organ (the best examples are the specific criteria for IgG4-related pancreatitis, sclerosing cholangitis, kidney disease and glandular disease). In 2012, Umehara et al, proposed a set of criteria for the diagnosis of systemic IgG4-RD designed to be used independently of the predominant organ involvement. The sensitivity and specificity of these criteria remain untested.

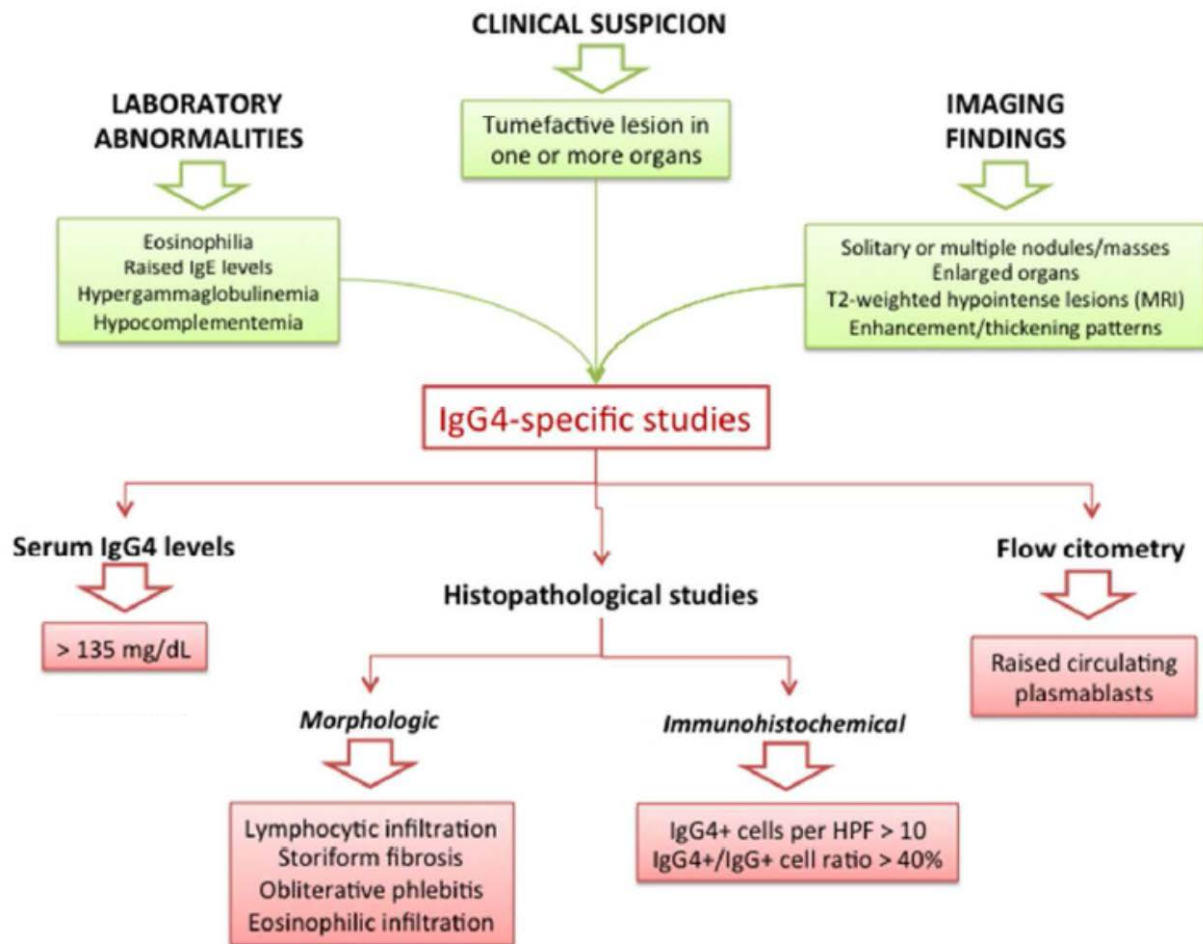

Diagnostic and therapeutic decision-making continues to be based on clinical experience and expert opinion (Mahajan et al, 2014) (Figure 1). Steroids are currently the cornerstone of treatment. In relapsing or refractory cases, Rituximab may be of help.

Greater understanding of the aetiopathogenesis of IgG4-RD, active multidisciplinary collaboration promoting international multicentre registries and clinical guidelines, and the development of more-specific therapies, may help improve the prognosis for patients with this emerging immune-mediated systemic disease.

Vasculitis: Classification, Secondary Forms and Mimics

Francesco Muratore, Neil Basu, Nicolò Pipitone

A previous version was coauthored by Neil Basu, Alfred D Mahr, Rosemary Hollick

LEARNING OBJECTIVES

- ➔ Describe the principles of classification of vasculitis
- ➔ Use the main tools available for the purposes of vasculitis classification
- ➔ Describe and explain the main primary vasculitides and their classification characteristics
- ➔ Describe and explain the main secondary vasculitides and their underlying aetiologies
- ➔ Evaluate the clinical features of those systemic conditions that may mimic systemic vasculitis and be able to distinguish conditions such as cholesterol embolism, infective endocarditis, atrial myxoma and fibromuscular dysplasia from vasculitis

1 Introduction

This chapter describes the current schemes for classifying and defining the systemic vasculitides. The strengths and weaknesses of these schemes are described together with an approach that enables them to be used consistently and logically.

The vasculitides are a heterogeneous group of relatively rare conditions that can occur independently—for example, granulomatosis with polyangiitis (Wegener's), or as a secondary feature of an established disease, such as rheumatoid arthritis. The word vasculitis means inflammation of blood vessels; the blood vessel is the primary site of inflammation. The pathological consequence of such inflammation is destruction of the vessel wall, seen histologically as fibrinoid necrosis, hence the term 'necrotising vasculitis'. Vasculitis may be localised to a single organ or vascular bed and be clinically insignificant but, more commonly, is generalised. Muscular arteries may develop focal or segmental lesions and these may be life threatening. The former (affecting part of the vessel wall) may lead to aneurysm formation and possible vessel rupture; segmental lesions (affecting the whole circumference) are more common and lead to stenosis or occlusion with distal infarction. Small-vessel vasculitis, by contrast, most commonly affects the skin, but may also cause dysfunction of internal organs.

The aetiology of vasculitis is unknown but is clearly multifactorial; among the influences on disease expression are ethnicity, genes (HLA and others), gender and environment (ultraviolet light, infections, toxins, drugs, allergy, smoking, etc).

1.1 Historical classifications

Kussmaul and Maier (1866) are generally accepted as providing the first description of 'periarteritis nodosa' when they described a patient with a systemic illness characterised by numerous nodules along the course of small muscular arteries. Earlier descriptions suggest that formal recording of the disease is at least 200 years old (Matteson, 1999). Zeek (1952) reviewed the literature relating to vasculitis and periarteritis nodosa and used the generic term 'necrotising angiitis' to indicate the specific damage to the blood vessel wall rather than the presence of inflammatory cells alone; she classified these into five distinct entities: (i) hypersensitivity angiitis, (ii) allergic granulomatous angiitis, (iii) rheumatic arteritis, (iv) periarteritis nodosa and (v) temporal arteritis. Most modern classifications are based on Zeek's work, which essentially combined histological changes and clinical features. Notable omissions from Zeek's classification were granulomatosis with polyangiitis (Wegener's), microscopic polyangiitis and Takayasu arteritis. Microscopic polyangiitis had been described by Davson et al (1948), but was not generally recognised until the 1990s. Granulomatosis with polyangiitis (Wegener's) and Takayasu arteritis were not fully described in the English literature until after 1953.

The most widely accepted classification system based on Zeek's work reflects dominant vessel size and association with antineutrophil cytoplasmic antibodies (ANCA) (table 1). This classification system also reflects broadly the therapeutic approaches that are applied to the different groups (table 2). The medium-vessel and small-vessel groups respond well to immunosuppression with cyclophosphamide and glucocorticoids, whereas the large-vessel group requires moderate-to-high-dose steroids and the small-vessel group sometimes requires only low-dose glucocorticoids.

Table 1 Classification of the vasculitic syndromes according to vessel size and ANCA. (Reproduced with permission from Scott and Watts, *Br J Rheumatol* 1994;33:897–9)

Dominant vessel	Primary	Secondary
Large arteries	Giant cell arteritis, Takayasu's arteritis	Aortitis associated with RA, infection (e.g., syphilis, TB)
Medium arteries	Classic PAN Kawasaki disease	Hepatitis B-associated PAN
Small vessels and medium arteries	Granulomatosis with polyangiitis (Wegener's)*, Churg–Strauss syndrome*, Microscopic polyangiitis*	Vasculitis secondary to RA, systemic lupus erythematosus, Sjögren's syndrome, drugs, infection (e.g., HIV)
Small vessels	Henoch–Schönlein purpura Cryoglobulinaemia Cutaneous leukocytoclastic angiitis	Drugs Hepatitis C associated Infection

*Diseases most commonly associated with ANCA and a significant risk of renal involvement, and most responsive to immunosuppression with cyclophosphamide.

ANCA, antineutrophil cytoplasmic antibodies; HIV, human immunodeficiency virus; PAN, polyarteritis nodosa; RA, rheumatoid arthritis; TB, tuberculosis.

Table 2 Relation between vessel size and response to induction treatment. (Reproduced with permission from Scott and Watts, *Br J Rheumatol* 1994;33:897–9)

Dominant vessels involved	Glucocorticoids alone	Cyclophosphamide + glucocorticoids	Others
Large arteries	++	–	+
Medium arteries	+	++	++*
Small vessels and medium arteries	+	+++	+
Small vessels	+	±	++

*Includes plasmapheresis, antiviral therapy for hepatitis B-associated vasculitis and intravenous immunoglobulins for Kawasaki disease.

1.2 1990 American College of Rheumatology classification criteria

There are no validated diagnostic criteria for systemic vasculitis. However, the American College of Rheumatology (ACR) presented classification criteria in 1990. They proposed criteria for the classification of seven types of systemic vasculitis: Takayasu arteritis (table 3), giant-cell arteritis (table 4), granulomatosis with polyangiitis (Wegener's) (table 5), polyarteritis nodosa (table 6), eosinophilic granulomatosis with polyangiitis (Churg–Strauss) (table 7), hypersensitivity vasculitis (table 8) and IgA vasculitis (Henoch–Schönlein) (table 9).

Table 3 American College of Rheumatology classification criteria for Takayasu arteritis

Criterion	Definition
1. Age <40 years old	Development of symptoms or signs related to Takayasu arteritis at age <40 years
2. Claudication of extremities	Development and worsening of fatigue and discomfort in muscles of one or more extremity while in use, especially the upper extremities
3. Decreased brachial arterial pulse	Decreased pulsation of one or both brachial arteries
4. Blood pressure difference >10 mm Hg	Difference of >10 mm Hg in systolic blood pressure between arms
5. Bruit over subclavian arteries or aorta	Bruit audible on auscultation over one or both subclavian arteries or abdominal aorta
6. Arteriogram abnormality	Arteriographic narrowing or occlusion of the entire aorta, its proximal branches, or large arteries in the proximal upper or lower extremities, not due to atherosclerosis, fibromuscular dysplasia or similar causes; changes usually focal or segmental

For purposes of classification, a patient shall be said to have Takayasu arteritis if at least three of these six criteria are present. The presence of any three or more criteria yields a sensitivity of 90.5% and specificity of 97.8% (Arend et al, 1990).*

Table 4 American College of Rheumatology classification criteria for giant-cell arteritis

Criterion	Definition
1. Age at onset >50 years	Development of symptoms or findings beginning aged ≥50 years
2. New headache	New onset, or new type, of localised pains in the head
3. Temporal artery abnormality	Temporal artery tenderness to palpation or decreased pulsation, unrelated to atherosclerosis of cervical arteries
4. Increased ESR	ESR >50 mm in first hour by Westergren method
5. Abnormal artery biopsy	Biopsy specimen with artery showing vasculitis characterised by a predominance of mononuclear infiltration or granulomatous inflammation

For purposes of classification, a patient shall be said to have giant-cell arteritis if at least three of these five criteria are present. The presence of any three or more criteria yields a sensitivity of 93.5% and specificity of 91.2% (Hunder et al, 1990).*

ESR, erythrocyte sedimentation rate.

Table 5 American College of Rheumatology classification criteria for granulomatosis with polyangiitis (Wegener's)

Criterion	Definition
1. Nasal or oral inflammation	Development of painful or painless oral ulcers or purulent or bloody nasal discharge
2. Abnormal chest radiograph	Chest radiograph showing the presence of nodules, fixed infiltrates or cavities
3. Urinary sediment	Microhaematuria (>5 red cells per high power field) or red cell casts in urinary sediment
4. Granulomatous inflammation on biopsy	Histological changes showing granulomatous inflammation within the wall of an artery or in the perivascular or extravascular area (artery or arteriole)

For purposes of classification, a person shall be said to have granulomatosis with polyangiitis (Wegener's) if at least two of these four criteria are present. The presence of any two or more criteria yields a sensitivity of 88.2% and specificity of 92.0% (Leavitt et al, 1990).*

Table 6 American College of Rheumatology classification criteria for polyarteritis nodosa

Criterion	Definition
1. Weight loss	Loss of ≥ 4 kg of body weight since the illness began, not because of dieting or other factors
2. Livedo reticularis	Mottled reticular pattern over the skin of portions of the extremities or torso
3. Testicular pain or tenderness	Pain or tenderness of the testicles, not the result of infection, trauma or other causes
4. Myalgias, weakness or leg tenderness	Diffuse myalgias (excluding shoulder or hip girdle) or weakness of muscles or tenderness of leg muscles
5. Mononeuropathy or polyneuropathy	Development of mononeuropathy, multiple mononeuropathies or polyneuropathy
6. Diastolic BP >90 mm Hg	Development of hypertension with diastolic BP >90 mm Hg
7. Raised blood urea or creatinine	Raised blood urea nitrogen >40 mg/dL or creatinine 1.5 mg/dL, not because of dehydration or obstruction
8. Hepatitis B virus	Presence of hepatitis B surface antigen or antibody in serum
9. Arteriographic abnormality	Arteriogram showing aneurysms or occlusion of the visceral arteries, not due to arteriosclerosis, fibromuscular dysplasia or other non-inflammatory causes
10. Biopsy of small or medium-sized artery containing polymorphonuclear neutrophils	Histological changes showing the presence of granulocytes or granulocytes and mononuclear leucocytes in the artery wall

For purposes of classification, a patient shall be said to have polyarteritis nodosa if at least three of these 10 criteria are present. The presence of any three or more criteria yields a sensitivity of 82.2% and specificity of 86.6% (Lightfoot et al, 1990). BP, blood pressure.*

Table 7 American College of Rheumatology classification criteria for Churg–Strauss syndrome

Criterion	Definition
1. Asthma	History of wheezing or diffuse high-pitched rales on expiration
2. Eosinophilia	Eosinophilia >10% on white cell differential count
3. Mononeuropathy or polyneuropathy	Development of mononeuropathy, multiple mononeuropathies or polyneuropathy (i.e., glove/stocking distribution) attributable to systemic vasculitis
4. Pulmonary infiltrates, non-fixed	Migratory or transient pulmonary infiltrates on radiographs (not including fixed infiltrates), attributable to a systemic vasculitis
5. Paranasal sinus abnormality	History of acute or chronic paranasal sinus pain or tenderness or radiographic opacification of the paranasal sinuses
6. Extravascular eosinophils	Biopsy including artery, arteriole or venule showing accumulations of eosinophils in extravascular areas

For purposes of classification, a person shall be said to have Churg–Strauss syndrome if at least four of these six criteria are present. The presence of any four or more criteria yields a sensitivity of 85.0% and specificity of 99.7% (Masi et al, 1990).*

Table 8 American College of Rheumatology classification criteria for hypersensitivity vasculitis

Criterion	Definition
1. Age at disease onset >16 years	Development of symptoms age >16 years
2. Medication at disease onset	Medication was taken at the onset of symptoms, which might have been a precipitating factor
3. Palpable purpura	Slightly raised purpuric rash over one or more areas of the skin, does not blanch with pressure and is not related to thrombocytopenia
4. Maculopapular rash	Flat and raised lesions of various sizes over one or more areas of the skin
5. Biopsy including arteriole and venule	Histological changes showing granulocytes in a perivascular or extravascular location

For purposes of classification, a patient shall be said to have hypersensitivity vasculitis if at least three of these five criteria are present. The presence of any three or more criteria yields a sensitivity of 71.0% and specificity of 83.9% (Calabrese et al, 1990).*

Table 9 American College of Rheumatology classification criteria for Henoch–Schönlein purpura

Criterion	Definition
1. Palpable purpura	Slightly raised purpuric rash over one or more areas of the skin not related to thrombocytopenia
2. Bowel angina	Diffuse abdominal pain worse after meals, or bowel ischaemia, usually bloody diarrhoea
3. Age at onset <20 years	Development of first symptoms at age ≤20 years
4. Wall granulocytes on biopsy	Histological changes showing granulocytes in the walls of arteries or venules

For purposes of classification, a patient shall be said to have Henoch–Schönlein purpura if at least two of these four criteria are present. The presence of any two or more criteria yields a sensitivity of 87.1% and specificity of 87.7% (Mills et al, 1990).*

The clinical and laboratory features of 807 patients were analysed, criteria being sought that would distinguish one individual disease from another. The findings in one group were compared with those in the remaining groups. The sensitivity rates varied considerably from 71.0% to 95.3% and from 78.7% to 99.7% for specificity (Fries et al, 1990*; Rao et al, 1998). Eosinophilic granulomatosis with polyangiitis (Churg–Strauss), giant-cell arteritis and Takayasu arteritis had the most sensitive criteria. Hypersensitivity vasculitis was the least well-defined condition, and these patients are now usually classified as having cutaneous leukocytoclastic angiitis or drug-associated vasculitis. The criteria were subsequently tested against a cohort of patients with systemic vasculitis and performed poorly (Rao et al, 1998). The ACR scheme has two major weaknesses: first, it does not include microscopic polyangiitis (this condition was not well recognised in the 1980s when the scheme was being developed) and second, it does not include ANCA (which were not widely used as a diagnostic tool in the 1980s).

1.3 Chapel Hill Consensus Conference

In 1994, the Chapel Hill Consensus Conference (CHCC) produced definitions for vasculitis. They included for the first time microscopic polyangiitis, but were not intended as classification or diagnostic criteria. Like the ACR criteria, ANCA were not included. They also recognised that histological data would not be available for all patients, especially when the clinical condition of the patient might preclude obtaining appropriate biopsies or the sample might not be representative and thus might miss salient histological features. This is particularly a problem for focal lesions such as granulomas. The concept of surrogate markers of vasculitis was therefore introduced. In addition, the potential importance of ANCA in diagnosis was recognised, but not included in the definitions. The result has been that although the ACR criteria and CHCC definitions are widely used, there is no agreement as to how they should be applied.

The CHCC definitions have recently been modified following an international consensus meeting held in 2011 to reflect changes in our understanding of the aetiopathogenesis of vasculitis (Jennette et al, 1994*). A new tree hierarchy was developed which recognised that some conditions cannot be simply classified by vessel size (table 10) (Jennette et al, 2013*). ANCA-associated vasculitis was recognised as a specific type of small-vessel vasculitis together with immune-complex-mediated vasculitis. The hierarchy was expanded to include vasculitis affecting vessels of variable size, single-organ vasculitis and vasculitis associated with either systemic disease or specific aetiologies. A new nomenclature was adopted, with a move away from eponyms towards names reflecting pathology or aetiopathogenesis following the introduction of the term GPA for Wegener's granulomatosis. The name 'eosinophilic granulomatosis with polyangiitis' was adopted for Churg–Strauss syndrome and 'IgA vasculitis' for IgA vasculitis (Henoch–Schönlein). Definitions were developed for new categories of conditions, including single-organ vasculitis, vasculitis associated with specific aetiologies including systemic disease (rheumatoid arthritis, systemic lupus erythematosus) and aetiologies such as

infection (cryoglobulinaemia, hepatitis B and C), or drugs (e.g., propylthiouracil) (table 10) (Jennette et al, 2013*).

Table 10 Names and definitions of vasculitides adopted by the Chapel Hill Consensus Conference on the nomenclature of systemic vasculitis*. (Reproduced with permission from Jennette et al, *Arthritis Rheum*, 2013;65:1–11*)

Large vessel vasculitis.	Description
Giant cell (temporal) arteritis	Granulomatous arteritis of the aorta and its major branches, with a predilection for the extracranial branches of the carotid artery. Often involves the temporal artery. Usually occurs in patients older than 50 years and often is associated with polymyalgia rheumatica
Takayasu's arteritis	Granulomatous inflammation of the aorta and its major branches. Usually occurs in patients younger than 50 years
Medium-sized vessel vasculitis.	
Polyarteritis nodosa [†] (classic polyarteritis nodosa)	Necrotising inflammation of medium-sized or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries or venules
Kawasaki disease	Arteritis involving large, medium-sized, small arteries, and associated with mucocutaneous lymph node syndrome. Coronary arteries are often affected. Aorta and veins may be involved. Usually occurs in children
Small vessel vasculitis.	
Granulomatosis with polyangiitis (Wegener's) [‡]	Granulomatous inflammation involving the respiratory tract, and necrotising vasculitis affecting small to medium-sized vessels (e.g., capillaries, venules, arterioles and arteries). Necrotising glomerulonephritis is common
Eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome) [‡]	Eosinophil-rich and granulomatous inflammation involving the respiratory tract, necrotising vasculitis affecting small to medium-sized vessels, and associated with asthma and eosinophilia
Microscopic polyangiitis [†] (microscopic polyarteritis) [‡]	Necrotising vasculitis, with few or no immune deposits, affecting small vessels (i.e., capillaries, venules or arterioles). Necrotising arteritis involving small and medium-sized arteries may be present. Necrotising glomerulonephritis is very common. Pulmonary capillaritis often occurs
Henoch–Schönlein purpura	Vasculitis, with IgA-dominant immune deposits, affecting small vessels (i.e., capillaries, venules or arterioles). Typically involves skin, gut and glomeruli, and is associated with arthralgia or arthritis
Essential cryoglobulinaemic vasculitis	Vasculitis, with cryoglobulin immune deposits, affecting small vessels (i.e., capillaries, venules or arterioles), and associated with cryoglobulins in serum. Skin and glomeruli are often involved
Cutaneous leukocytoclastic angiitis	Isolated cutaneous leukocytoclastic angiitis without systemic vasculitis glomerulonephritis

**Large vessel refers to the aorta and the largest branches directed towards the major body regions (e.g., to the extremities and the head and neck); medium-sized vessel refers to the main visceral arteries (e.g., renal, hepatic, coronary and mesenteric arteries); small vessel refers to venules, capillaries, arterioles and the intraparenchymal distal arterial radicals that connect with arterioles. Some small and large vessel vasculitides may involve medium-sized arteries, but large and medium-sized vessel vasculitides do not involve smaller arteries. † Preferred term. ‡ Strongly associated with antineutrophil cytoplasmic antibodies.*

1.4 Problems of the ACR criteria and CHCC definitions for vasculitis

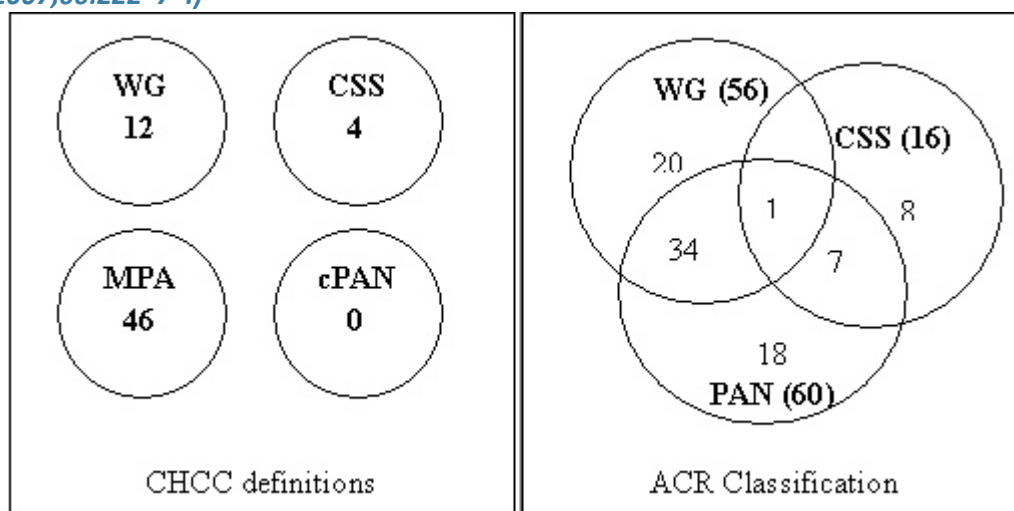

There have been two major attempts at adapting the CHCC definitions for use in classification. Hagen et al used the 1994 CHCC definitions in a study assessing the standardisation of ANCA assays (Hagen et al, 1998). The same methods have been used subsequently in the European trials of immunosuppressive therapy in ANCA-associated vasculitis. Their method accepted that histology was not available for all patients and used surrogate markers for vasculitis. For granulomatosis with polyangiitis (Wegener's) they described four groups: (i) histologically proved vasculitis with granulomata and/or giant cells (with or without nephritis); (ii) clinical evidence of airway involvement and histological evidence of crescentic and/or necrotising glomerulonephritis with few or no immune deposits; (iii) clinical evidence of airways disease, no renal involvement but biopsy evidence of vasculitis in any other organ; and (iv) clinical evidence of airways involvement without histology. Renal limited vasculitis (idiopathic rapidly progressive glomerulonephritis) was considered to be histologically proved crescentic and/or necrotising glomerulonephritis with few or no immune deposits, or histologically proved small-vessel vasculitis. Microscopic polyangiitis was defined in the same way but with evidence of additional extra renal manifestations compatible with vasculitis but no airway manifestations of granulomatosis with polyangiitis (Wegener's). Classic polyarteritis nodosa required proof of arterial vasculitis (angiography or biopsy) and was excluded by the presence of small-vessel vasculitis or crescentic glomerulonephritis. Eosinophilic granulomatosis with polyangiitis (Churg–Strauss) required histological evidence of vasculitis, crescentic glomerulonephritis, granulomata in combination with asthma, and eosinophilia. There was no attempt to validate this scheme and use of ANCA was specifically excluded.

Sorensen et al evaluated the use of the 1994 CHCC definitions with surrogate markers as diagnostic classification criteria in 118 patients with primary and secondary vasculitis (Sorensen et al, 2000). They found the definitions unhelpful for diagnosis but proposed new criteria for the diagnosis of granulomatosis with polyangiitis (Wegener's) and eosinophilic granulomatosis with polyangiitis (Churg–Strauss) based upon histology, surrogate markers of vasculitis and the presence of proteinase 3 (PR3)-ANCA in granulomatosis with polyangiitis (Wegener's).

A study applied the criteria suggested by Sorensen et al to a cohort of patients with primary systemic vasculitides enrolled via a prospective vasculitis register. The criteria suggested for microscopic polyangiitis were not helpful; 50 of 55 patients who fulfilled the ACR classification for granulomatosis with polyangiitis (Wegener's) could also be classified as having microscopic polyangiitis by the Sorensen criteria (Lane et al, 2002). On review of these patients, it was clear that they had been excluded by the Sorensen criteria owing to the presence of eosinophilia. It was therefore suggested that a level of eosinophilia $<1.5 \times 10^9/L$ could be accepted in granulomatosis with polyangiitis (Wegener's).

Another study applied the ACR criteria (for granulomatosis with polyangiitis (Wegener's), eosinophilic granulomatosis with polyangiitis (Churg–Strauss) and polyarteritis nodosa) and 1994 CHCC definitions to a cohort of 99 patients from a well-defined population. There was significant overlap between diagnoses (i.e., 34 patients could be classified as having both granulomatosis with polyangiitis (Wegener's) and polyarteritis nodosa, seven eosinophilic granulomatosis with polyangiitis (Churg–Strauss) and polyarteritis nodosa, and one eosinophilic granulomatosis with polyangiitis (Churg–Strauss), granulomatosis with polyangiitis (Wegener's) and polyarteritis nodosa) and 11 patients were unclassifiable (figure 1A). Applying the 1994 CHCC definitions without surrogate markers/ANCA resulted in no overlapping diagnoses, but 37 patients could not be classified (figure 1B) (Lane et al, 2005). Some patients with eosinophilic granulomatosis with polyangiitis (Churg–Strauss) were unclassifiable using both the CHCC definitions and ACR criteria, but were classifiable with the use of additional clinically based but invalidated Lanham criteria (Lanham et al, 1984).

Figure 1 *Overlap diagnosis of vasculitis. Results of the application of the (A) American College of Rheumatology (ACR) (1990) criteria for granulomatosis with polyangiitis (Wegener's) (GPA), Churg–Strauss syndrome (CSS), microscopic polyangiitis (MPA) and cutaneous polyarteritis nodosa (cPAN) and (B) Chapel Hill Consensus Conference (CHCC) definitions for a cohort of 99 patients. (Reproduced from Watts et al, Ann Rheum Dis 2007;66:222–7*.)*

1.5 Other sets of classification criteria

1.5.1 European Medicines Agency classification algorithm

An attempt has been made to reconcile these differences and produce a consensus method for the application of both the ACR scheme and the 1994 CHCC definitions for granulomatosis with polyangiitis (Wegener's), eosinophilic granulomatosis with polyangiitis (Churg–Strauss), polyarteritis nodosa and microscopic polyangiitis (Watts et al, 2007*). An algorithm has been developed by consensus (figure 2), which classifies patients into a single category. The algorithm incorporates both ANCA surrogate markers. The algorithm has been validated using paper cases and has been shown to successfully classify patients into a single category.

Later, the algorithm was tested in large cohort of 550 Chinese patients with primary systemic vasculitis, 493 of whom were ANCA positive (Liu et al, 2008). In accordance with the findings reported in the original study (Watts et al, 2007*), the algorithm successfully achieved the aim of classifying the patients into a single category with only 20 (3.6%) patients unclassified. When the algorithm was used, no patients were classified as having polyarteritis nodosa compared with four using the 1994 CHCC definition. Patients with a classification of microscopic polyangiitis by CHCC (n = 363) could be divided into granulomatosis with polyangiitis (Wegener's) (n = 37), microscopic polyangiitis (n = 324) and eosinophilic granulomatosis with polyangiitis (Churg–Strauss) (n = 2). The number of unclassified patients was reduced from 56 to 20. It is important to recognise that the algorithm was developed and validated for epidemiological studies rather than for clinical trials. Its use in the latter setting requires validation.

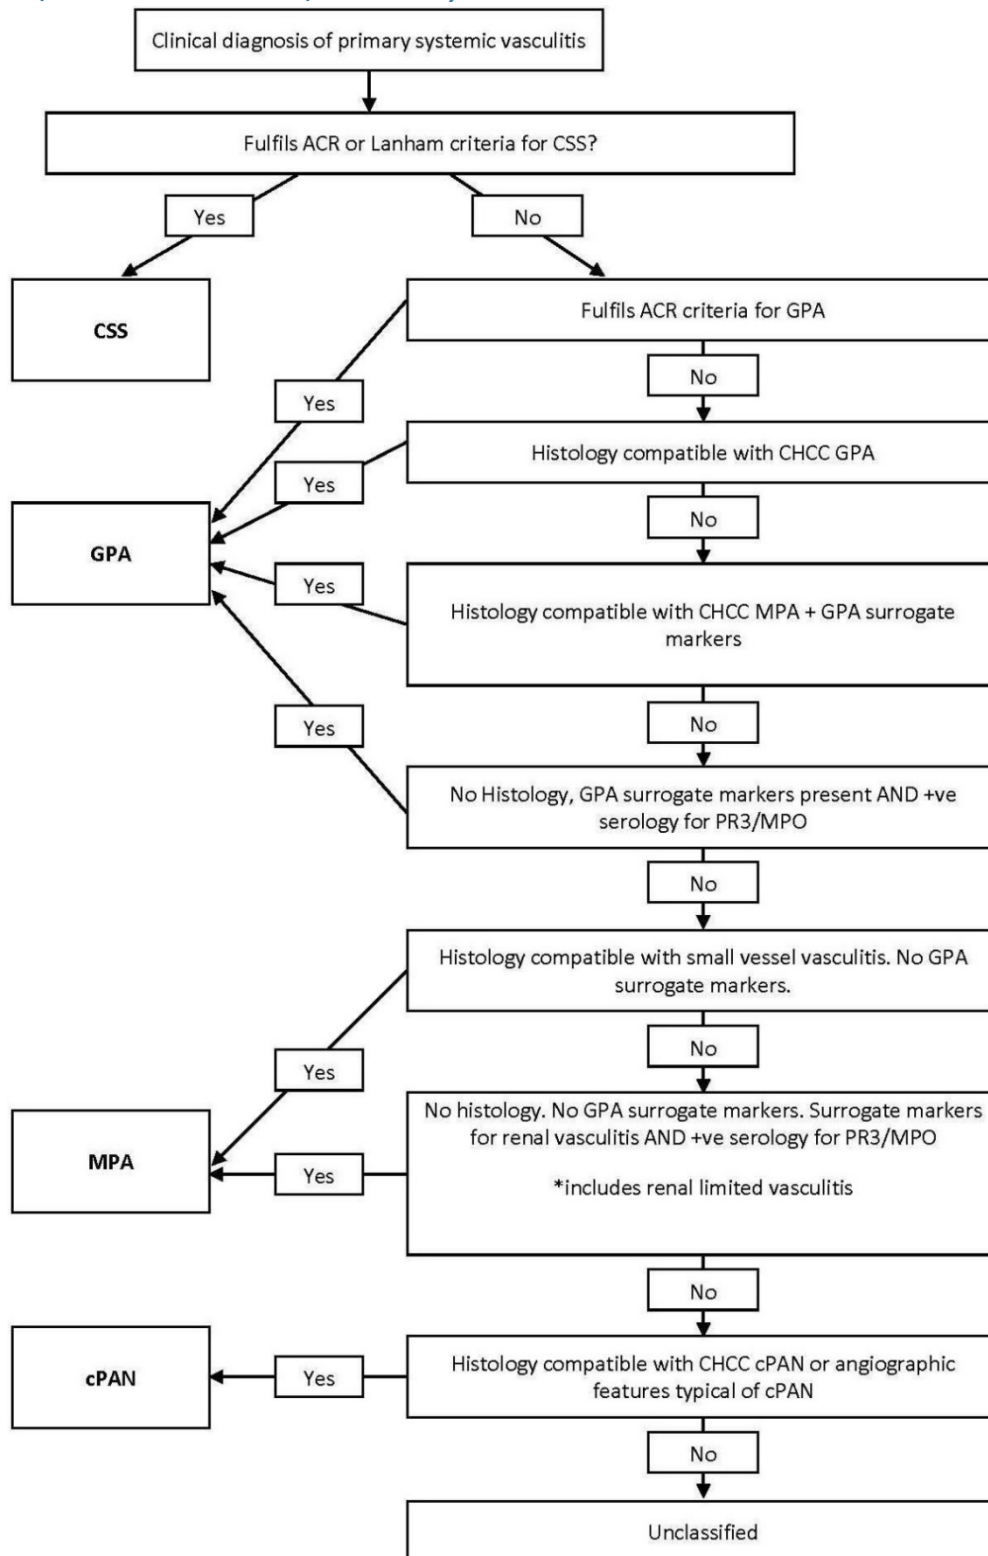

1.5.2 EULAR/PReS working group criteria for childhood vasculitis

A EULAR/Paediatric Rheumatology European Society (PReS) working group has developed classification criteria for childhood vasculitis (Ozen et al, 2010; Ruperto et al, 2010). Childhood vasculitis was classified according to vessel size, with small-vessel diseases subdivided into granulomatous and non-granulomatous. Classification criteria were developed for IgA vasculitis (Henoch–Schönlein), childhood polyarteritis nodosa, granulomatosis with polyangiitis (Wegener's) and Takayasu arteritis. These criteria have been validated (Ozen et al, 2010).

The existing ACR criteria for IgA vasculitis (Henoch–Schönlein) were modified to remove the age criterion, and the presence of IgA deposits on histopathology was highlighted. The presence of palpable purpura was made mandatory, and at least one of abdominal pain, positive histopathology, arthritis/arthralgia and renal involvement had to be present.

The existing ACR criteria for polyarteritis nodosa were felt by consensus to be unsuitable for the classification of childhood polyarteritis nodosa—in particular, because streptococcal infections are often felt to be causative in children. Hepatitis B virus (HBV) infection is not a criterion (as this is rarely a feature in children with improved vaccination protocols). The criteria require the presence of either histopathological evidence of vasculitis or positive angiographic evidence plus one of skin involvement, myalgia, hypertension, neuropathy and renal involvement.

Figure 2 European Medicines Agency algorithm for classification of vasculitis. ACR, American College of Rheumatology; CHCC, Chapel Hill Consensus Conference; CSS, Churg–Strauss syndrome; MPA, microscopic polyangiitis; MPO, myeloperoxidase; PAN, polyarteritis nodosa; PR3, proteinase 3; PSV, primary systemic vasculitis; WG, Wegener's granulomatosis, now known as granulomatosis with polyangiitis. (Reproduced from Watts et al, *Ann Rheum Dis* 2007;66:222–7*.)

The ACR criteria for granulomatosis with polyangiitis (Wegener's) were modified to include two new criteria: (i) the presence of subglottic, tracheal or endobronchial stenosis; and (ii) the presence of high-titre ANCA (PR3 or myeloperoxidase (MPO)) or positive ANCA (cytoplasmic or perinuclear) by indirect immunofluorescence. Microscopic polyangiitis was not classified by the ACR; the EULAR/PreS group adopted the CHCC definition, but added an association with MPO-ANCA to the definition.

EULAR/PreS modified the ACR criteria for Takayasu arteritis by making the presence of angiographic abnormalities mandatory. This can be assessed using conventional contrast angiography, CT or magnetic resonance angiography. Hypertension (age appropriate) was added, as this may be the sole presenting feature of Takayasu arteritis in childhood; the age criterion was removed.

1.5.3 French Vasculitis Study Group criteria for the diagnosis of polyarteritis nodosa

One of the main problems with the ACR criteria is that they do not include microscopic polyangiitis and consequently, the ability to distinguish between polyarteritis nodosa and microscopic polyangiitis is poor.

Henegar et al conducted a study of 949 patients with systemic vasculitis in the French Vasculitis Study Group database with the aim of developing better criteria for polyarteritis nodosa (Henegar et al, 2008). The study included 262 patients with polyarteritis nodosa (108 HBV-associated polyarteritis nodosa), 256 with granulomatosis with polyangiitis (Wegener's), 207 with microscopic polyangiitis, 150 with Churg–Strauss syndrome, 18 with cryoglobulinaemic vasculitis and 56 with other types of vasculitis. Of the original 10 ACR criteria, they retained only three: presence of HBV antigen, arteriographic abnormalities and polyneuropathy. They introduced five negative criteria, including negative indirect immunofluorescence detection of ANCA (table 11). These criteria had 70.6% sensitivity against all vasculitis controls with 92.3% specificity. When compared against microscopic polyangiitis, there was 89.7% sensitivity and 83.1% specificity. These criteria remain to be validated as diagnostic criteria.

Table 11 The French Vasculitis Study Group minimal set of low-redundant polyarteritis nodosa predictive criteria. (Reproduced with permission from Henegar et al, *Arthritis Rheum* 2008;58:1528–38)

Criterion	PAN association	Definition
1. HBV infection	Positive	Markers reflecting active HBV replication, such as the presence of HBeAg in serum and/or the detection of HBV DNA at >105 copies/mL
2. ANCA positivity	Negative	Presence of ANCA in serum, as determined by indirect immunofluorescence
3. Asthma	Negative	Previous history of asthma
4. ENT signs	Negative	Signs of maxillary sinusitis or otitis media
5. Cryoglobulin positivity	Negative	Detection of cryoglobulins in serum
6. Glomerulopathy	Negative	Signs of glomerulopathy, such as proteinuria and/or haematuria with or without renal insufficiency, not due to urinary tract infection, urolithiasis, or haematological or other non-glomerular causes
7. Arteriographic abnormalities	Positive	Arteriogram showing aneurysms or occlusions of the visceral arteries, not due to arteriosclerosis, fibromuscular dysplasia and other non-inflammatory causes
8. Mono-/polyneuropathy	Positive	Development of polyneuropathy, multiple mononeuropathies or polyneuropathy

ANCA, antineutrophil cytoplasmic antibodies; ENT, ear, nose and throat; HBeAg, hepatitis B e antigen; HBV, hepatitis B virus; PAN, polyarteritis nodosa.

1.5.4 Lanham criteria for eosinophilic granulomatosis with polyangiitis (Churg–Strauss)

The invalidated ‘Lanham’ criteria for eosinophilic granulomatosis with polyangiitis (Churg–Strauss) (box 1) are sometimes used for classification purposes in combination with the ACR classification criteria and the CHCC definition (Churg–Strauss).

Box 1 Lanham criteria for Churg–Strauss syndrome

1. Asthma
 2. Peripheral blood eosinophilia $>1.5 \times 10^9/L$
 3. Systemic vasculitis involving two or more extrapulmonary organs.
- All three items are required; biopsy evidence of granuloma is not required.

1.5.5 International Study Group criteria for Behçet’s disease

Behçet’s disease is a rare chronic inflammatory multisystem disorder characterised by recurrent oral and genital ulcers and skin, articular, eye, vascular or central nervous system disease. Various classification systems have been developed for Behçet’s disease. The International Study Group criteria (table 12), which were published as diagnostic criteria, are the most frequently employed classification system for Behçet’s disease. A large international effort undertaken to revise these criteria, named ‘International criteria for Behçet’s

disease', was recently published. These criteria added neurological and vascular involvement as classifying criteria and included a new item weighting system (table 13).

Table 12 International Study Group diagnostic criteria for Behçet's disease. (Reproduced with permission from International Study Group for Behçet's disease, Lancet 1990;335:1078–80)

Criterion	Definition
Recurrent oral ulceration	Minor aphthous, major aphthous or herpetiform ulceration seen by physician or patient, which recurred at least three times in one 12-month period
Plus two of:	
1. Recurrent genital ulceration	Aphthous ulceration or scarring seen by the physician or patient
2. Eye lesions	Anterior uveitis, posterior uveitis or cells in vitreous on slit-lamp examination; or: retinal vasculitis seen by ophthalmologist
3. Skin lesions	Erythema nodosum seen by physician or patient, pseudofolliculitis, or papulopustular lesions; or acneiform nodules seen by physician in post adolescent patients not receiving glucocorticoid treatment
4. Positive pathergy test	Read by physician at 24–48 h

For the diagnosis to be made, a patient must have recurrent oral ulceration plus at least two of the other findings in the absence of other clinical explanations (sensitivity: 91%, specificity: 96%).

Table 13 International criteria for Behçet's disease. (Reproduced from International Team for the Revision of the International Criteria for Behçet's Disease, J Eur Acad Dermatol Venereol. 2014;28:338-47)

Sign/symptom	Point
Ocular lesions	2
Genital aphthosis	2
Oral aphthosis	2
Skin lesions	1
Neurological manifestations	1
Vascular manifestations	1
Positive pathergy test*	1*

**Pathergy test is optional and the primary scoring system does not include pathergy testing. However, where pathergy testing is conducted one extra point may be assigned for a positive result.*

A patient scoring ≥ 4 points is classified as having Behçet's disease (sensitivity: 93.9%, specificity: 92.1%)

1.5.6 American Heart Association diagnostic criteria for Kawasaki disease

Kawasaki disease is an acute febrile mucocutaneous and lymph node illness affecting children aged <5 years, mainly of Asian descent. The most widely used criteria for Kawasaki disease are those established by the American Heart Association (box 2). These criteria were labelled as being diagnostic criteria.

Box 2 American Heart Association diagnostic criteria for Kawasaki disease

Fever of at least 5 days' duration

Presence of four of the following principal features:

1. Changes in extremities
2. Polymorphous exanthema
3. Bilateral conjunctival injection
4. Changes in the lips and oral cavity
5. Cervical lymphadenopathy

Patients with fever and fewer than four principal clinical features can be diagnosed as having Kawasaki disease when coronary artery disease is detected by two-dimensional echocardiography or coronary angiography.

Exclusion of other diseases with similar findings, including measles, scarlet fever, drug reactions, Stevens–Johnson syndrome, other febrile viral exanthemas, Rocky Mountain spotted fever, Staphylococcal scalded skin syndrome, toxic shock syndrome, juvenile rheumatoid arthritis, leptospirosis, mercury poisoning.

Source: Dajani et al, *Circulation* 1993;87:1776–80.

1.6 Perspectives

There is still, however, a need for new validated classification and diagnostic criteria for granulomatosis with polyangiitis (Wegener's), microscopic polyangiitis and polyarteritis nodosa. New criteria for IgA vasculitis (Henoch–Schönlein) and cutaneous leukocytoclastic angiitis are also required because of the low specificity of the existing ACR criteria. The criteria for giant-cell arteritis and Takayasu arteritis have high specificity and sensitivity and are generally accepted. A research agenda has been developed and a major international effort, the Diagnostic and Classification criteria in Vasculitis Study (DCVAS), is underway to develop new classification and diagnostic criteria (Basu et al, 2010; Luqmani et al, 2011; Watts et al, 2011). 2017 provisional classification criteria for granulomatosis with polyangiitis (Wegener's) have been presented at the 2016 annual meeting of the American College of Rheumatology.

2 Secondary vasculitis and vasculitis mimics

A heterogeneous group of diseases may mimic systemic vasculitis and if treated as such, lead to unnecessary morbidity. The key conditions discussed include infection-related vasculitis, especially vasculitis related to hepatitis B and C. Other conditions include cholesterol embolism, infective endocarditis, atrial myxoma and fibromuscular dysplasia.

Vasculitis occurring in association with rheumatoid arthritis is described in chapter 9 and the in-depth online discussion.

Vasculitis may be idiopathic (e.g., granulomatosis with polyangiitis (Wegener's)), occur in the setting of established rheumatic disease or malignancy, or be triggered by other exogenous stimuli such as drugs and infection. There are also a number of conditions that can mimic vasculitis.

2.1 Infection and vasculitis

The notion that infection could trigger vasculitis was first suggested over 100 years ago. A wide variety of organisms have been implicated (table 14). Possible mechanisms for infection-related vasculitis include: (i) direct microbial toxicity either by endothelial invasion (e.g., *Rickettsia*, *Bartonella* or cytomegalovirus) or the effect of microbial toxins on endothelium; and (ii) an immune-mediated process by either humoral (immune complex, e.g., hepatitis C and cryoglobulinaemia) or cellular responses (Somer and Finegold, 1995). Infection may also be a consequence of intensive immunosuppression for primary vasculitis.

Table 14 Infection and vasculitis

Vessel involved		Infection
Large arteries	Bacterial	<i>Staphylococcus</i> , <i>Salmonella</i> , mycobacteria, <i>Streptococcus</i>
	Spirochaetal	<i>Treponema pallidum</i>
	Fungal	Coccidiomycosis
Medium arteries	Bacterial	Group A streptococcus, mycobacteria
	Viral	HBV, HCV, HIV, parvovirus B19
Small vessels and medium arteries	Bacterial	<i>Streptococcus</i>
	Viral	HBV, HCV, HIV, CMV
Small vessel (leukocytoclastic)	Bacterial	<i>Staphylococcus</i> , <i>Salmonella</i> , mycobacteria, <i>Streptococcus</i> , <i>Yersinia</i> , <i>Neisseria</i> , <i>Rickettsiae</i>
	Viral	HIV, CMV, herpes zoster, parvovirus B19, HBV, HCV

CMV, cytomegalovirus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus.

2.1.1 Viral infections

Viral infection may be followed by several different outcomes: (i) viral clearance; (ii) latency with periodic reactivation—for example, herpes zoster; or (iii) persistent viral replication with stable or progressive course—for example, hepatitis B and C.

HBV infection has been firmly associated with polyarteritis nodosa for 40 years (Trepo and Thivolet, 1970). In areas endemic for HBV infection, up to 95% of polyarteritis nodosa cases are associated with HBV infection, with an incidence of 77 per million population (McMahon et al, 1989).

In France, falling HBV infection rates have been correlated with a decrease in HBV-associated polyarteritis nodosa. In the 1970s, 38% of cases of polyarteritis nodosa were HBV-related compared with 17% in 2000 (Guillevin et al, 2005*). This reduction is attributable to the introduction of HBV vaccination and screening of blood donations. The commonest cause is now injecting drug use. In the Alaskan population with HBV-associated polyarteritis nodosa, D is the most common HBV genotype (Hurlburt et al, 2007). The clinical characteristics of HBV-associated polyarteritis nodosa are similar to those seen in non-HBV-associated classic polyarteritis nodosa apart from more frequent gastrointestinal involvement, extraglomerular renovascular disease with malignant hypertension and orchitis in HBV-associated polyarteritis nodosa. The most common

features are mononeuritis multiplex (83.5%), gastrointestinal (57%), renal tract (38%), skin (31%) and hypertension (31%). HBV-associated polyarteritis nodosa usually develops within 12 months of infection; hepatitis is mild before the development of polyarteritis nodosa. Angiography shows the typical microaneurysms and/or stenosis in the coeliac axis and renal vasculature. ANCA are not associated with HBV-associated polyarteritis nodosa.

HBV-associated polyarteritis nodosa should be identified, as treatment with antiviral drugs is effective. Excellent initial results were achieved using a combination of antiviral agents (vidarabine or interferon α -2a) (table 15). The preferred protocol is lamivudine (100 mg/day) combined with plasma exchange to remove immune complexes (de Menthon and Marr, 2011). This is accompanied by a short course of glucocorticoids. The outcome for patients treated with this approach is excellent and only 6% relapse. Seroconversion from hepatitis B e antigen to hepatitis B e antibody is usually achieved and is associated with a decreased risk of relapse. Gastrointestinal involvement is associated with reduced survival. The 10-year survival is around 60% (Guillevin et al, 2005*; Pagnoux et al, 2006*).

Table 15 Major viruses associated with vasculitis and their treatment

Virus	Type of vasculitis	Standard treatment
HBV	PAN	Short GC, PE, lamivudine
HCV	Cryoglobulinaemic vasculitis	Short GC, antiviral therapy (DAAs or IFN α and ribavirin) \pm PE
HIV	PAN large/medium/small vessel vasculitis cerebral vasculitis	Short GC with ARV \pm PE
Parvovirus B19	PAN	GC
	HSP-like	GC and/or IVIg
Varicella zoster	Retinitis meningoencephalomyelitis	Acyclovir \pm GC
CMV	Retinitis	Valganciclovir, ganciclovir or foscarnet
	Colitis PAN	

ARV, antiretroviral drugs; CMV, cytomegalovirus; DAAs, direct-acting antiviral agents; GC, glucocorticoid; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HSP, Henoch–Schönlein purpura; IFN α , interferon α ; IVIg, intravenous immunoglobulin; PAN, polyarteritis nodosa; PE, plasma exchange.

Hepatitis C virus (HCV) was first identified in 1989. There is a strong association between HCV infection and essential mixed cryoglobulinaemia, with 80–90% of such patients positive for anti-HCV antibodies (Agnello et al, 1992). Type II cryoglobulins with a monoclonal IgM- κ is most typically associated with cryoglobulinaemic vasculitis. Circulating HCV RNA has been identified in the peripheral blood of patients with cryoglobulinaemia. HCV has been identified within cutaneous vasculitic lesions and has been selectively concentrated together with its specific antibody in cryoprecipitates.

The most common clinical feature of HCV-associated cryoglobulinaemic vasculitis is purpura, and less often urticaria, livedo, exanthema, acral necrosis, leg ulcers, arthralgias, arthritis, muscle weakness and

polyneuropathy (typically subacute, distal, symmetrical or asymmetrical, motor and/or sensory polyneuropathy, or acute mononeuritis multiplex). The majority of patients have hypocomplementaemia (90%) and circulating rheumatoid factor (70%) (Landau et al, 2008); they are ANCA negative.

Hypocomplementaemia is a useful feature to distinguish HCV-associated disease from ANCA-associated systemic vasculitis. HCV infection has also been associated with a polyarteritis nodosa-type vasculitis with involvement of medium-sized arteries and a necrotising vasculitis (Saadoun et al, 2007). Renal disease is common and is distinguishable from ANCA-associated vasculitis. The characteristic lesion is membranoproliferative glomerulonephritis with intracapillary thrombi, which contain cryoglobulin precipitates.

Severe or life-threatening disease should be treated with steroids and cyclophosphamide with or without plasma exchange (table 15), while awaiting the slower response to antiviral agents. Less severe disease (arthralgias, purpura, sensory neuropathy) is treated with antiviral agents combined with short course of glucocorticoids (Pagnoux et al, 2006*). Pegylated IFN α and ribavirin are effective. Ribavirin alone cannot suppress viral replication. Antiviral therapy options have been recently expanded with the introduction of direct-acting antiviral agents (DAAs). These new drugs are providing the opportunity for a dramatic change in the anti-HCV therapeutic approach, eradicating HCV with shorter therapy duration, minimal side-effects and efficacy approaching 100%. Limited, but essentially concordant data suggest that IFN-free antiviral therapies with DAAs are safe, generally well tolerated and effective in patients with HCV-associated cryoglobulinaemic vasculitis (Zignego et al, 2017). Anti-CD20 therapy may have a useful role in selected cases (Saadoun et al, 2008a; Saadoun et al, 2008b).

The introduction of the highly effective DAAs may improve the prognosis of HCV-related vasculitis, that is not as good as for HBV-associated polyarteritis nodosa, with deaths due to infection or renal disease (Landau et al, 2010).

Human immunodeficiency virus (HIV) infection has been associated with a wide variety of autoimmune and inflammatory vascular conditions. Vasculitis may either be directly related to HIV infection or be a consequence of secondary opportunistic infection, particularly with cytomegalovirus or tuberculosis (Chetty, 2001). Vasculitis is a rare manifestation of HIV infection (Guillevin, 2008) and can occur at any stage of the infection. A number of patterns of vasculitis have been described, including polyarteritis nodosa-like, hypersensitivity vasculitis and large-vessel disease (Guillevin, 2008). No clear treatment strategy has been developed. Glucocorticoids remain the mainstay of treatment for HIV vasculitis. Conventional immunosuppressant drugs should be avoided where possible as they may allow the development of opportunistic infection, especially if the CD4 T cell count is $<200 \times 10^6/L$ (Guillevin, 2008). Thus most regimens advocate suppression of HIV replication with combination antiviral therapy, possibly with adjunctive plasma exchange (Pagnoux et al, 2006*).

Parvovirus B19 infection, especially during the viraemic phase, has been associated with a small-vessel vasculitis that may mimic IgA vasculitis (Henoch–Schönlein). Parvovirus infection can be detected by serological tests. Most patients recover spontaneously, but for severe episodes glucocorticoids may be required.

Varicella zoster infection may result in an acute vasculitis affecting the central nervous system (CNS), retinal and/or thyroidal small vessels and, rarely, the skin and kidney. Encephalitis or myelitis may be seen in immunocompromised patients. Cerebral angiography may show an arteritis. Virus may be detected in cerebrospinal fluid or meningeal biopsy by polymerase chain reaction. Treatment is with acyclovir.

Cytomegalovirus (CMV)-associated vasculitis usually occurs in severely immunocompromised patients with HIV or after a bone marrow transplant. CMV seems to directly infect endothelial cells. Commonly affected organs include the gut, CNS and skin. Typical CMV inclusions can be seen in endothelial cells, suggesting a direct effect on small vessels. CMV vasculitis is life threatening and requires intravenous ganciclovir or foscarnet.

2.1.2 Bacterial infections

Direct endothelial invasion by pyogenic organisms (e.g., *Staphylococcus* and *Streptococcus*) is a well-recognised cause of vasculitis. The spectrum of bacteria associated with vasculitis has changed over the past three decades with more unusual infections being reported—for example, *Mycobacterium fortuitum*, *Enterobacteriaceae* and *Salmonella*. Blood cultures are often positive and the responsible organism can be identified in more than 50% of cases (Pagnoux et al, 2006*). Skin biopsy of affected skin may yield micro-organisms. There is a predisposing condition in around 60% of cases, of which the most common is diabetes mellitus. Infection often occurs at the site of previous damage by atherosclerosis or surgery.

The vascular response to direct infection depends on the organism and site of infection. In large arteries, infection leads to an erosive arteritis with mycotic aneurysm formation. Aortitis is an uncommon manifestation of *Streptococcus pneumoniae* infection. *Salmonella* aortitis is well recognised and usually presents with fever together with abdominal and back pain. The site most frequently affected is the abdominal aorta followed by the thoracic aorta. Predisposing conditions include injecting drug use, hypertension, diabetes mellitus and myelodysplastic syndrome (Soravia-Dunand et al, 1999). Treatment is with intravenous antibiotics combined with surgery.

Direct bacterial infection of small arteries and arterioles causes a necrotising vasculitis or thrombosis. *Neisseria gonorrhoea*, *Neisseria meningitidis* and *Streptobacillus moniliformis*, for example, may directly infect vascular endothelium causing maculopapular or purpuric skin lesions. Biopsies of early lesions show a small-vessel vasculitis with mononuclear cells, neutrophils, leukocytoclastic and necrosis. The organisms can be cultured from an aspirate of the lesions.

2.1.3 *Mycobacterial infections*

Vessels of any size can be affected by tuberculous infection, with veins more often involved than arteries (Somer and Finegold, 1995). The typical clinical lesion is erythema nodosum. Tuberculous vasculitis of large and small vessels manifests as a granulomatous pan arteritis or thrombophlebitis. Acid-fast bacilli may be found in, or adjacent to, the vessel wall.

Distribution of the vascular lesions of *Mycobacterium leprae* infection is focal and involves arteries and veins with equal frequency. The most common site is small vessels—for example, erythema nodosum leprosum, or the vasa vasorum of large vessels. The clinical consequences of vasculitis are rarely significant.

2.1.4 *Spirochaetal infection*

Treponema pallidum is a well-recognised cause of aortitis, with aneurysm formation and the development of aortic incompetence. These lesions are now rare since the introduction of penicillin, but have begun to reappear because of the spread of HIV infection. The primary histological changes are in the vasa vasorum with endarteritis and perivascular infiltration with lymphocytes and plasma cells. Infection occurs early in the disease and organisms lie dormant in the aortic wall. Spirochetes can, however, only rarely be detected in tissue. Symptomatic aortic disease occurs as a feature of tertiary syphilis, about 10–30 years after the initial infection. Diagnosis is based on the radiographic appearance and serological tests.

2.1.5 *Rickettsial infection*

Vascular lesions are a prominent feature of some rickettsial infections, particularly Rocky Mountain spotted fever, epidemic typhus and scrub typhus. In humans, the organism (an obligate intracellular bacterium) is usually found in vascular endothelium and in some cases, vascular smooth muscle. The pathology of the vascular lesion in *Rickettsia rickettsii* (Rocky Mountain spotted fever) follows a characteristic pattern. In the early stages, endothelial cell swelling is seen in association with intracellular rickettsiae. Later vasculitis with increased vascular permeability, haemorrhage and, occasionally, thrombosis occurs with immunoglobulin and complement deposition. Vasculitis most typically presents with an extensive maculopapular rash in Rocky Mountain spotted fever that can, if not treated, result in involvement of the kidney, lung and brain. The diagnosis is based on clinical features with subsequent serological confirmation.

2.1.6 *Fungal infections*

Fungal infections may cause vasculitis by direct spread into the vessel wall with formation of a mycotic aneurysm. This usually occurs in patients who are already severely immunocompromised from other diseases. Fungi such as *Coccidioides immitis* may also cause a local CNS vasculitis, presenting acutely with stroke-like lesions; these patients have a high mortality and require aggressive antifungal treatment.

2.2 Vasculitis and malignancy

2.2.1 Malignancies associated with concurrent or subsequent development of vasculitis

Acute vasculitis may be the presenting feature of an undiagnosed malignancy. Most types of malignancy have been associated with vasculitis (table 16). However, a review of 2800 patients with vasculitis and 69 000 patients with cancer identified only 69 patients with both vasculitis and malignancy (Hutson and Hoffman, 2000). There were 12 patients in whom the cancer and vasculitis occurred within 12 months. Six patients had solid organ tumours, four lymphoma, one leukaemia and one multiple myeloma. The most common type of vasculitis was cutaneous leukocytoclastic angiitis ($n = 7$), followed by giant-cell arteritis ($n = 2$), polyarteritis nodosa ($n = 2$) and granulomatosis with polyangiitis (Wegener's) ($n = 1$).

Table 16 Vasculitis and malignancy

Malignancies associated with subsequent development of vasculitis	Vasculitis types associated with malignancy	Malignancy developing in patients with a diagnosis of primary systemic vasculitis
Myelodysplasia	Granulomatosis with polyangiitis (Wegener's)	Renal cell carcinoma
Lymphoma	Polyarteritis nodosa	Colon adenocarcinoma
Hairy cell leukaemia	Microscopic polyangiitis	Skin
Myeloma	Henoch–Schönlein purpura	Leukaemia
	Cutaneous leukocytoclastic vasculitis	Lymphoma
		Bladder carcinoma*

*Associated with cyclophosphamide treatment.

Several epidemiological studies have examined the occurrence of malignancy in patients with granulomatosis with polyangiitis (Wegener's). A malignancy was found in 23/477 patients with granulomatosis with polyangiitis (Wegener's) compared with 18/479 patients with rheumatoid arthritis (Tatsis et al, 1999). Seven patients with renal cell carcinoma were found in the granulomatosis with polyangiitis (Wegener's) group and only one in the rheumatoid arthritis group. Among those, simultaneous occurrence of cancer was found in 14 of the 23 patients with granulomatosis with polyangiitis (Wegener's) (in 5/7 patients with renal carcinoma) and only one of the 18 patients with rheumatoid arthritis. The prevalence of other cancers was not different from that of the control population.

In the UK, a retrospective study compared 200 patients with granulomatosis with polyangiitis (Wegener's) or microscopic polyangiitis with 129 patients with IgA vasculitis (Henoch–Schönlein), 333 patients with systemic lupus erythematosus and a normal control population (Pankhurst et al, 2004). The patients with granulomatosis with polyangiitis (Wegener's), microscopic polyangiitis and IgA vasculitis (Henoch–Schönlein) all had a focal segmental necrotising glomerulonephritis or vasculitis with associated IgA. The rate of malignancy in all patients was increased compared with that of the normal control population (relative risk

(RR) 7.5; 95% CI 5.0 to 11.4); this increased risk was present for both groups with ANCA-associated vasculitis (RR = 6.0; 3.7 to 9.7) and IgA vasculitis (Henoch–Schönlein) (RR = 5.3; 2.4 to 11.5). The most common malignancy was colon cancer (IgA vasculitis (Henoch–Schönlein): two patients, microscopic polyangiitis: three patients). This confirmed the association of ANCA-associated vasculitis with solid malignancies but could not confirm the association with renal cancer.

Conversely, one Danish study did not demonstrate an increased rate of cancer before the onset of granulomatosis with polyangiitis (Wegener's) (Faurschou et al, 2009).

IgA vasculitis (Henoch–Schönlein) has been associated with malignancy, but the risk is not greater than for other types of vasculitis or autoimmune disease (Pertuiset et al, 2000). The association appears to be with solid tumours rather than haematological malignancies. Pertuiset et al compared patients with IgA vasculitis (Henoch–Schönlein) with and without malignancy; those with malignancy were more likely to be older, male, have more joint involvement and fewer preceding infections (Pertuiset et al, 2000). It is worth noting that IgA vasculitis (Henoch–Schönlein) is characteristically a disease of younger people and therefore if it presents in the elderly, a coexisting malignancy should be considered.

A case–control study showed that patients with giant-cell arteritis have fewer cancers before diagnosis than controls and no increased risk after diagnosis (Kermani et al, 2010a; Kermani et al, 2010b).

Vasculitis associated with lymphoproliferative disorders is usually localised to the skin. In a series of 172 adults with cutaneous vasculitis, only four (2.3%) were associated with malignancy. All four malignancies were haematological (Blanco et al, 1998). Hamidou et al analysed the frequency of ANCA and vasculitis in a prospective cohort study of 60 patients with myelodysplastic syndromes and 140 patients with lymphoid malignancies (Hamidou et al, 2000). Among the 60 patients with myelodysplasia, six had ANCA-negative systemic vasculitis, one ANCA-positive systemic vasculitis, one giant-cell arteritis and one relapsing polychondritis. Of the 140 patients with lymphoid malignancies, two had ANCA-negative systemic vasculitis, two had leukocytoclastic vasculitis in association with tuberculous infection, and one giant-cell arteritis. There was no association with hepatitis B or C infection.

Hairy cell leukaemia is a rare lymphoproliferative disease characterised by the presence of mononuclear cells with hair-like cytoplasmic projections in peripheral blood, bone marrow, spleen and liver. Hairy cell leukaemia has been strongly associated with systemic necrotising vasculitis, especially polyarteritis nodosa and cutaneous leukocytoclastic angiitis (Hasler et al, 1995*). Direct infiltration of vessel walls by hairy cells has been seen in some cases. In most cases, the leukaemia is diagnosed first and the interval between the two diagnoses may be several years. The vasculitis is not usually the cause of death, which is the result of complications of leukaemia and its treatment. Bayer-Garner and Smoller reviewed 2357 cases of multiple myeloma and

identified eight patients with leukocytoclastic vasculitis. There was a preponderance of IgG myeloma, which paralleled the immunoglobulin secretion (Bayer-Garner and Smoller, 2003).

In conclusion, vasculitis may be the presenting feature of malignancy, but this is uncommon. The strongest link is between cutaneous vasculitis and haematological malignancy.

2.2.2 Malignancy developing in patients with a diagnosis of primary systemic vasculitis

A much more common situation is the development of malignancy in patients receiving immunosuppressive therapy for an established diagnosis of vasculitis (table 16). Importantly, these occurrences do not fall into the category of secondary, malignancy-associated vasculitides but rather reflect the carcinogenicity of immunosuppressive therapy. Other pathogenic mechanisms, such as chronic immune stimulation or loss of control of emerging cancer clones owing to iatrogenic immunodeficiency, may also play a role in the development of cancers in treated patients with vasculitis.

The treatment of vasculitis with cyclophosphamide has long been associated with the development of bladder cancer, with up to a 31-fold increase in patients with granulomatosis with polyangiitis (Wegener's) receiving long-term cyclophosphamide therapy (Talar-Williams et al, 1996; Knight et al, 2004*). The risk is associated with total dose exposure and whether uro-epithelial protective agents such as mesna were used (Monach et al, 2010). Lymphoma, squamous cell skin cancer and leukaemias may also be consequences of immunosuppressive therapy. Westman et al, in a study from Sweden of patients with granulomatosis with polyangiitis (Wegener's) or microscopic polyangiitis and renal involvement, reported a fivefold increase in the risk of bladder cancer, which again was associated with cyclophosphamide therapy (Westman et al, 1998). Recent data from the French Vasculitis Study Group registry suggest that intermittently administered intravenous cyclophosphamide treatment has a much lower risk of urinary tract cancer than daily oral cyclophosphamide (Le Guenno et al, 2011).

In another study from Sweden, Knight et al described a population-based cohort of 1065 patients with granulomatosis with polyangiitis (Wegener's) from an inpatient registry and, through linkage to the Swedish Cancer Register, identified those in the cohort developing cancer (Knight et al, 2002). The cohort had a twofold increase in cancer overall, with a standardised incidence ratio (SIR) = 4.8 for bladder cancer, SIR = 7.3 for squamous cell carcinoma of the skin, SIR = 5.7 for leukaemia and SIR = 4.2 for lymphoma. There was no increased risk for other solid malignancies. A Danish study observed significantly increased rates of acute myeloid leukaemia, bladder cancer and non-melanoma skin cancers. Leukaemias and bladder cancers developed 6.9–18.5 years after cyclophosphamide therapy was started. The highest risk for leukaemia and bladder cancer was in patients who had received >36 g of cyclophosphamide (Faurschou et al, 2008).

Further insight into the incidence of malignancies among patients treated for granulomatosis with polyangiitis (Wegener's) and microscopic polyangiitis was provided based on long-term follow-up data of newly diagnosed cases enrolled in European clinical trials since 1995. This study suggested a 1.6-fold higher incidence of cancer at any sites among the patients with vasculitis compared with the general population data. Non-melanoma skin cancer was the only cancer type with a significantly increased incidence. These findings suggested that cancer risk might have decreased as a consequence of the modern trend towards using shorter courses of cyclophosphamide (Heijl et al, 2011*).

In the Wegener's Granulomatosis Etanercept Trial study of etanercept versus placebo plus conventional immunosuppression for granulomatosis with polyangiitis (Wegener's), an increased frequency of solid malignancies was found in the etanercept-treated group; whether this was a result of the combination of etanercept with previous cyclophosphamide exposure was hypothesised but uncertain (Stone et al, 2006). The malignancies seen in this study included colonic cancer, cholangiocarcinoma, breast carcinoma and renal cell carcinoma. Pertinently, an analysis of post-trial follow-up data confirmed the increased cancer incidence among these patients with granulomatosis with polyangiitis (Wegener's) as compared with the general population. However, this increased risk was not different between the etanercept and placebo groups (Silva et al, 2011).

2.2.3 Vasculitis mimicking malignancy

Vasculitis may also mimic malignancy. A large mass of inflammatory tissue associated with constitutional symptoms may be misdiagnosed as a malignancy. Differentiation between lymphoma and granulomatosis with polyangiitis (Wegener's) of the upper airways can be particularly difficult.

2.3 Drug-induced vasculitis

Drug-induced vasculitis is probably one of the commoner causes of vasculitis. A very wide range of drugs together with vaccines and desensitisation procedures have been reported as causing a vasculitic reaction; however, many of these are isolated case reports and it is not possible to conclusively prove a causal relationship. Recently more definite associations have been described—in particular, with propylthiouracil, hydralazine and leukotriene antagonists. A number of recreational drugs have also been reported to cause vasculitis, including heroin, cocaine and methamphetamine, and have been particularly associated with cerebral vasculitis. More recently, levamisole-contaminated cocaine has been reported as causing a multisystem vasculitis mimicking GPA. The majority of patients develop an isolated small-vessel vasculitis; medium-vessel involvement occurs uncommonly and large-vessel involvement is rare. The pathogenesis is generally thought to be the result of specific pathogenic mechanisms, immune complex formation, hypocomplementaemia and cell-mediated mechanisms with T cell activation.

The clinical and pathological presentation of drug-induced vasculitis is indistinguishable from that of other types of small-vessel vasculitis. The most common skin lesion is purpura, which may be palpable. The rash is symmetrical and often affects the extremities. The lesions are the same age and disappear within several weeks of drug withdrawal. They may scar or cause haemosiderosis. The most common histological appearance is a leukocytoclastic vasculitis. Other laboratory findings are non-specific with leucocytosis, hypocomplementaemia and raised acute phase response. An eosinophilia is suggestive of a drug aetiology but is also a typical feature of Churg–Strauss syndrome. ANCA may be present and they sometimes reflect systemic involvement.

Vasculitis associated with ANCA has been attributed to a number of drugs, including hydralazine and propylthiouracil, and is especially associated with anti-MPO specificity (Choi et al, 2000*; Gao et al, 2008). Choi et al reviewed 250 patients with MPO-positive systemic vasculitis and detected hydralazine, propylthiouracil, allopurinol, penicillamine or sulfasalazine use in 18 cases within 9 months before the onset of disease (Choi et al, 2000*).

Leukotriene receptor antagonists including zafirlukast, montelukast and pranlukast have been linked to the onset of eosinophilic granulomatosis with polyangiitis (Churg–Strauss). Wechsler et al described 12 patients with steroid-dependent asthma who developed eosinophilic granulomatosis with polyangiitis (Churg–Strauss) after withdrawal of steroids permitted by zafirlukast or montelukast (Wechsler et al, 2000). All the patients fulfilled criteria for eosinophilic granulomatosis with polyangiitis (Churg–Strauss). There has subsequently been some debate as to whether the introduction of leukotriene inhibitors in patients with asthma precipitates eosinophilic granulomatosis with polyangiitis (Churg–Strauss) de novo, or whether these drugs given for difficult-to-control or progressive asthma permit a reduction in steroids and therefore unmask previously undiagnosed eosinophilic granulomatosis with polyangiitis (Churg–Strauss) (Nathani et al, 2008), or whether use of these drugs simply reflects the commonly severe asthma preceding this vasculitis requiring the prescription of multiple anti-asthma agents. The incidence rate for eosinophilic granulomatosis with polyangiitis (Churg–Strauss) was found to be similar for both zafirlukast and montelukast users (60/million patient-years), and also similar to that found in an asthmatic population not treated with leukotriene inhibitors (Loughlin et al, 2002). In contrast, findings from two case–control studies confirmed an association between antileukotrienes use and the development of eosinophilic granulomatosis with polyangiitis (Churg–Strauss), but comparable relationships were also identified for other drugs used to treat asthma—for example, inhaled long-acting β agonists or oral glucocorticoids (Harrold et al, 2007; Hauser et al, 2008*). These findings support the suggestion that antileukotrienes are merely a marker of the severity and gradual worsening of the asthma preceding eosinophilic granulomatosis with polyangiitis (Churg–Strauss) onset, rather than a real culprit in the disease. The same explanation may hold true for the very similar story which emerged after the introduction of monoclonal anti-IgE antibody (omalizumab) for the treatment of asthma, with case reports of eosinophilic

granulomatosis with polyangiitis (Churg–Strauss) developing after treatment with omalizumab for asthma (Wechsler et al, 2009).

The treatment of drug-induced hypersensitivity is unclear. Most cases respond simply to withdrawal of the inducing drug. Reported cases tend to reflect the severe end of the spectrum and reported treatments include glucocorticoids, plasmapheresis and cyclophosphamide.

2.4 Vaccination

Vaccine-induced vasculitis has been rarely described after some antiviral vaccines. Vasculitis occurring after recombinant HBV vaccination has been reported in 13 cases. Initial clinical features developed within 6–7 weeks of vaccination. Affected organs were most typically the skin, joints, retina and muscle; renal involvement was not seen. However, a large review concluded that there was no strong supportive evidence to support such a causal link (Begier et al, 2004). Vaccine-induced vasculitis, in particular eosinophilic granulomatosis with polyangiitis (Churg–Strauss), has been noted after tetanus, influenza, hepatitis B, rubella and smallpox vaccination (Guillevin et al, 1999). A detailed review of the occurrence of autoimmune reaction to commonly administered vaccines concluded that there was no association (Schattner, 2005).

2.5 Vasculitis secondary to inflammatory rheumatic disease

2.5.1 Rheumatoid vasculitis

Rheumatoid vasculitis is dealt with in chapter 9 on rheumatoid arthritis.

2.5.2 Spondyloarthropathies

Aortitis may complicate the seronegative spondyloarthropathies—in particular, ankylosing spondylitis and Reiter’s syndrome. The aortic ring and ascending aorta are the typical sites of involvement but distal aortitis has been described. Rarely, aortic incompetence occurs early in the disease, but does so with increasing frequency with disease duration, perhaps in up to 10% of cases at 30 years.

Echocardiography shows thickening of the aortic leaflets, subaortic echo-dense bumps and aortic root densities. Histologically, there is thickening of the aortic valve cusps and aorta, together with lymphocytic infiltration in the aortic wall and fibrosis of the aortic root (Townend et al, 1991).

Treatment of the inflammatory process with immunosuppressive agents has been suggested, but there are no relevant controlled data—in particular, on the need or not for aortic valve replacement.

2.5.3 Other connective tissue diseases

Vascular involvement in systemic lupus erythematosus, Sjögren's syndrome and the antiphospholipid antibody syndrome is described in chapters 20, 25 and 22, respectively.

2.6 Vasculitis mimics

Systemic vasculitis presents with numerous widespread manifestations and diagnosis is based on a combination of clinical, laboratory and histopathological features. The clinical features alone are not always diagnostic and a variety of other diseases can masquerade as systemic vasculitis (table 17). These mimics usually present with multiorgan illness or evidence of vascular damage, or a combination of both. Biopsy of involved organs is, therefore, important to identify non-inflammatory vascular changes such as embolism or thrombosis. Angiographic features including aneurysms, although typical of polyarteritis nodosa, can occur in other conditions such as myxoma and bacterial endocarditis.

Table 17 Vasculitis masquerades

Mimicking:	Clinical signs
1. Systemic multisystem disease	
Infection	Subacute bacterial endocarditis
	Neisseria
	Rickettsiae
Malignancy	Metastatic carcinoma
	Paraneoplastic
Other	Sweet's syndrome
	Scurvy
2. Occlusive vasculopathy	
Embolic	Cholesterol crystals
	Atrial myxoma
	Infection
Thrombotic	Antiphospholipid syndrome
	Procoagulant states
	Calciphylaxis
Others	Ergot
	Radiation
	Degos
	Severe Raynaud's syndrome
	Acute digital loss
3. Angiographic	
Aneurysmal	Fibromuscular dysplasia
	Neurofibromatosis
Occlusion	Coarctation

2.6.1 Cholesterol crystal embolism

Cholesterol crystal embolism has been recognised for more than a century but remains underdiagnosed. Risk factors for cholesterol embolism are male sex, age >60 years, white race, hypertension, tobacco use, diabetes

mellitus, anticoagulation therapy with either heparin or warfarin, and thrombolysis (Scolari et al, 2000; Meyrier, 2006). Cholesterol embolism may occur spontaneously or after trauma to the aortic wall during vascular surgery or angiographic procedures. The clinical consequences of cholesterol crystal embolism are variable. Embolisation may be completely asymptomatic and the diagnosis made only at renal biopsy, or may cause an ischaemic digit or a multisystem disease that mimics systemic vasculitis. The distribution of end-organ damage depends on the location of the original atherosclerotic plaques.

Clinically significant renal involvement occurs in around 50% of patients; the onset of renal disease after the triggering event may be immediate but can be more insidious with a delay of weeks or months. There may be acute renal impairment following massive embolisation; alternatively, there may be a gradual deterioration in renal function caused by showers of cholesterol emboli (Scolari et al, 2000; Meyrier, 2006).

Cutaneous manifestations are typically ischaemic digits, particularly the toes from abdominal atheroma emboli, and livedo reticularis affecting the legs (figure 3). The ischaemia usually presents as sudden onset of a small, cool, cyanotic and painful area of the foot (usually the toe). The lesions are tender to touch and may progress to ulceration, digital infarction and gangrene. The peripheral pulses are usually well preserved despite the digital cyanosis. Other common features include abdominal pain, CNS involvement, fever and weight loss.

Figure 3 *Cutaneous infarct caused by cholesterol embolisation mimicking vasculitis.*

Laboratory investigations are often non-specific, including uraemia, thrombocytopenia, eosinophilia, raised erythrocyte sedimentation rate, hypocomplementaemia and disseminated intravascular coagulation. ANCA

are not usually detected in the serum (Scolari et al, 2000). Diagnosis is based on the clinical features with a typical history, supported by histological demonstration of the typical cholesterol clefts or cholesterol emboli in vessels (figure 4).

Treatment is aimed at halting the progression of tissue ischaemia and prevention of further embolisation. Anticoagulation should be avoided as this may exacerbate embolisation. Antiplatelet therapy is unsuccessful. Further endovascular procedures should be avoided (Hitti et al, 2008).

Figure 4 Histology findings from the same patient as in figure 3 showing typical clefts left by cholesterol deposits in small blood vessels.

2.6.2 Calciphylaxis

Calciphylaxis is rare but potentially fatal. It occurs in patients with chronic renal failure with secondary hyperparathyroidism. Disturbance of calcium and phosphate metabolism results in painful necrosis of the skin, subcutaneous tissue and acral gangrene. The appearance of the lesions is distinctive, but the pathogenesis remains uncertain. Correction of hyperphosphataemia or, occasionally, hypercalcaemia is vital, and parathyroidectomy, but also intravenous sodium thiosulfate, may be of benefit (Mathur et al, 2001; Malbos et al, 2013).

2.6.3 Cardiac myxoma

Cardiac myxomas are rare benign tumours most commonly found in the left atrium (90% of cases). Systemic manifestations seen in 90% of cases include fever, weight loss, Raynaud's phenomenon, clubbing, raised acute phase proteins and hypergammaglobulinaemia. Systemic embolisation occurs in 40%; emboli may be large enough to occlude the aortic bifurcation, while smaller emboli may remain viable and invade the vessel wall, resulting in aneurysm formation that mimics vasculitis. The diagnosis is made by echocardiography, which should be performed in all cases of suspected systemic vasculitis. Treatment is by surgical resection of the primary tumour and any emboli (Traill, 2003).

2.6.4 Infectious endocarditis

Infectious endocarditis is associated with both vasculitic and embolic phenomena. True vasculitic lesions are caused either by an immune complex vasculitis, the infectious agent or mycotic aneurysm formation by septic emboli where there is direct invasion of the vessel wall. Petechiae, strokes, splenic infarcts and glomerulonephritis are the most common extracardiac features. There is an immunological response with elevation of acute phase proteins, hypergammaglobulinaemia and autoantibody formation. The diagnosis is made by blood culture and echocardiography (Littler and Eykyn, 2003).

2.6.5 Fibromuscular dysplasia

Fibromuscular dysplasia is a vascular disease that affects small to medium-sized arteries. It is a non-inflammatory, non-atherosclerotic condition that occurs in younger people and women. Involvement of the renal arteries occurs in 60–75%, cervicocranial arteries in 25–30%, visceral arteries in 9% and peripheral arteries in 5% of cases (Slovut and Olin, 2004). Classification is dependent on the dominant arterial wall layer involved: intimal, medial or adventitial. The cause is unknown; smoking and hypertension are associated with an increased risk. Clinical manifestations reflect the arterial tree involved, with renovascular hypertension, renal infarction, dissection, transient ischaemic attacks and stroke. The diagnosis is made on the typical angiographic appearances with the classic 'string of beads' sign. Fibromuscular dysplasia—in particular, diffuse intimal disease, can occasionally be difficult to distinguish from vasculitis. There should not, however, be evidence of an acute phase response. Symptomatic stenotic lesions are treated by percutaneous transluminal angioplasty or bypass grafting, together with antiplatelet drugs. Hypertension should be treated according to national guidelines.

2.6.6 Chronic ergotism

Epidemic ergotism occurs after ingestion of grain contaminated with ergot (*Claviceps purpurea*) and was known in mediaeval times as St Antony's fire (Christopoulos et al, 2001). Painful gangrene of the peripheries occurs with loss of extremities. Critical mesenteric ischaemia can occur. Chronic ergotism can occur after long-

term use of ergotamine tartrate to treat migraine. Peripheral, carotid, coronary and visceral ischaemia may develop. The angiographic appearances may simulate vasculitis with irregular, long or short segmental stenosis. The diagnosis is dependent on a history of ergot consumption. The lesions may not be fully reversible on withdrawal of ergot.

2.6.7 Köhlmeier–Degos disease

Köhlmeier–Degos disease (malignant atrophic papulosis) is a rare and lethal condition which involves the skin, gut and nervous system. The typical skin lesions are circular and porcelain white with a depressed centre 4–8 mm in diameter with a slightly raised erythematous margin. The arterial lesion is luminal stenosis or occlusion caused by intimal proliferation and consequent thrombosis. Presentation is with acute abdominal pain (in association with the skin lesion), leading to bowel infarction. The multisystem nature of Köhlmeier–Degos disease mimics a vasculitis. The diagnosis is made on biopsy (Scheinfeld, 2007).

2.6.8 Cryofibrinogenaemia

Cryofibrinogenaemia comes about when a cryoprecipitate occurs in plasma which has been anticoagulated with oxalate, citrate or edetic acid (Saadoun et al, 2009). The cryoprecipitate is a complex which includes a number of plasma proteins, including fibrin, fibrinogen and fibrin split products. The cryofibrinogen is consumed in the clotting process and therefore, unlike a cryoglobulin, does not precipitate in cooled serum. Cryofibrinogenaemia may be asymptomatic but can present with purpura, skin necrosis, ulcers, gangrene, arthralgias, glomerulonephritis or a leukocytoclastic vasculitis and thus mimic a systemic vasculitis. Cryofibrinogenaemia may be primary or secondary to malignancy, infection or a connective tissue disease (figures 5 and 6). It is dealt with by avoidance of cold and treatment of the underlying condition, combined with immunosuppression, plasmapheresis and/or fibrinolytic drugs.

Figure 5 Digital gangrene in a patient with cryofibrinogenaemia secondary to malignancy.

Figure 6 Rash in patient with cryofibrinogenaemia secondary to malignancy.

2.6.9 Sweet's syndrome

Sweet's syndrome is a rare condition, otherwise known as acute febrile neutrophilic dermatosis (Cohen, 2007). It was originally described following respiratory infection (figure 7) but is more commonly seen in patients with malignancy. It may be precipitated by drugs—in particular, granulocyte-colony stimulating factor. The condition is characterised by fever, neutrophilia and tender erythematous cutaneous lesions (plaques, nodules and papules). The lesions may resemble a systemic vasculitis, especially in a febrile ill patient. Skin biopsy shows an intense infiltrate of mature neutrophils, typically in the upper dermis. Treatment is with glucocorticoids, which usually results in a rapid improvement.

Figure 7 Sweet's syndrome following a chest infection.

SUMMARY POINTS

- Vasculitides are inflammatory vessel diseases which include around 15–20 distinct entities.
- Vasculitides are categorised as primary (i.e., idiopathic) or secondary vasculitides.
- Vasculitides are further separated into three groups according to the size of the predominantly involved vessels (i.e., large, medium or small-vessel vasculitis).
- The most common causes of secondary vasculitides are malignancies, infections or drug exposure.
- Some vasculitis entities (e.g., polyarteritis nodosa) may present both as primary and as secondary vasculitis (e.g., HBV-related polyarteritis nodosa).
- Most cases of vasculitis are primary vasculitides, with vasculitis cases with a known underlying cause being less common in clinical practice.
- The 2011 Chapel Hill Consensus Conference nomenclature devised definitions for primary vasculitides.
- The 1990 American College of Rheumatology classification criteria cover seven vasculitis entities.
- For some vasculitis entities, classification remains problematic because their disease features overlap with one or several other vasculitis entities and/or because of the lack of highly accurate classification systems.
- It is important to consider vasculitis mimics in the differential diagnosis as they require different therapeutic approaches.

IN-DEPTH DISCUSSION I

Drug-associated vasculitis

LEARNING OUTCOMES

Drug-associated vasculitis (DAV) represents one the commonest forms of inflammatory vascular disease. Due to the distinct approach to their management, differentiation from other vasculitic syndromes is crucial.

Following this module, the student should be able to:

- i) Recognise the commonest drugs currently associated with the development of vasculitis
- ii) Describe the evaluation and management of DAV
- iii) Distinguish DAV from primary forms of systemic vasculitis

The putative causal relationship between pharmaceutical agents and vasculitic manifestations has been recognised for decades and the resultant syndromes are often referred to by varying terms including hypersensitivity, allergic and leukocytoclastic vasculitis. Such nomenclatures are neither specific nor accurate for vasculitis related to drug exposure and only serve to confuse. The most recent Chapel Hill Consensus Conference nomenclature provided a robust alternative, proposing ‘drug-associated vasculitis’ which can be further refined to reflect the likely causative agent and subsequent disease form (e.g. hydralazine-associated microscopic polyangiitis)[1].

A review of any pharmaceutical formulary makes it clear that most classes of drug can be implicated in vasculitic adverse events. This is not to say that vasculitis is a very common consequence of overall drug prescription per se. The majority of observations relate to occasional case reports regarding routinely prescribed drugs (e.g. statins [2]). Even among the more frequently cited drug culprits (e.g. anti-rheumatic biologicals) their occurrence can be described as uncommon at best - for example a prospective study of anti-TNF therapy identified only 5 cases of DAV among 278 patients with rheumatoid arthritis [3]. Conversely, DAV comprises a significant proportion of all vasculitis cases (a relatively uncommon presentation in itself), with drug reactions deemed attributable in 11% of all subjects submitted to ACR’s original 1990 classification study[4] and >20% of cutaneous vasculitis presentations[4-5].

Indeed the pathology is limited to the skin in the vast majority of cases where purpura and maculopapular rashes represent the commonest phenotypic features. In general, such manifestations tend to develop a few days to weeks after drug exposure and preferentially involve the lower limbs. Diagnosis is supported by cutaneous biopsy which can reveal a small vessel neutrophilic or lymphocytic vasculitis and any evidence for tissue eosinophilia reinforces the suspicion of a drug aetiology further. Tissue is equally important in excluding alternative diagnoses such as cholesterol emboli and specimens should be sent for immunofluorescence, e.g. to determine the possibility of IgA vasculitis (Henoch-Schönlein), and culture, e.g. to exclude tuberculosis.

Clearly the ultimate diagnosis of DAV is predicated upon evidence of a temporal relationship with the suspect drug. As mentioned, agents across the pharmaceutical spectrum are culpable and include alternative remedies and those used for recreational purposes. A thorough drug exposure history is vital with particular attention directed towards recent antibiotics, immunomodulators (including biologics), growth factors and anti-hypertensive prescriptions. Ultimately, withdrawal of the offending drug should result in the resolution (over weeks) of most cutaneous limited forms and in doing so provides confirmatory evidence of causality. In these situations the patient should be advised to avoid future exposure.

Not all patients present with cutaneous disease and even those **who** do may experience additional systemic manifestations. Thus a cornerstone of evaluation is to quantify disease extent. The development of systemic disease may take months or even years following initial drug exposure and patients can present with the catastrophic visceral involvement as commonly observed in primary systemic vasculitides. Importantly, simple drug withdrawal is not always sufficient to avoid organ damage in systemic forms and standard immunosuppressant regimes, such as cyclophosphamide and corticosteroids, may be required in severe cases. That said, the overall requirement of immunosuppressants for systemic DAV is substantially reduced compared to primary phenotypic counterparts and so it is crucial to be able to distinguish these.

The process of distinction is perhaps most challenging in those drugs inducing phenotypes similar to those observed among ANCA associated vasculitis (GPA, MPA, EGPA) since these patients quite often harbour serological evidence of ANCA as well. However, these tend to be simultaneously directed towards multiple antigens and typically at a much higher titre than observed in primary forms of the disease [6].

Among prescription drugs, hydralazine and propylthiouracil are most commonly related to the development of AAV-like syndromes.

The vasodilatory properties of hydralazine have been employed for many decades in the treatment of hypertension and cardiac failure. Its association with a pulmonary-renal syndrome characteristic of microscopic polyangiitis has been frequently reported and best recorded by a study of 30 consecutive cases of vasculitis presenting with very high titres of anti-MPO antibodies. On retrospective review, one third of these patients had been exposed to hydralazine [7]. In addition to MPO antibodies, ANCA directed towards human neutrophil elastase and lactoferrin are commonly identified as are homogenous anti-nuclear and anti-histone antibodies. This co-occurrence of vasculitis and SLE associated autoantibodies is often clinically translated with patients presenting with overlapping phenotypic features of DAV and drug associated SLE [8]. Although the precise mechanism of hydralazine induced immune dysfunction is unknown, it is intriguing to note the drug's recognised capacity for epigenetic modification (specifically as a non-nucleoside DNA methylation inhibitor). Thus it is possible that the drug may interfere with the expression of neutrophil constituents such as MPO and PR3 - currently thought to be pivotal in the pathogenesis of primary ANCA associated vasculitis [9].

The development of a pauci-immune crescentic glomerulonephritis following exposure to the anti-thyroid medication propylthiouracil (PTU) has been frequently noted. Other systems can be involved, especially the bone marrow (agranulocytosis) and high MPO-ANCA titres are invariably observed. Recent studies from China found that patients with PTU related vasculitis predicted female sex and younger age when compared to patients with primary ANCA associated vasculitis. In addition, the degree of renal involvement was less severe and overall prognosis much more favourable [10-11]. Again the precise mechanisms are unknown, although it may be that the drug or its intermediates stimulate ANCA production [9]. It is certainly interesting to note that ANCA is evident in over a quarter of patients receiving long term PTU therapy and that titres often resolve following drug cessation [12].

In addition, leukotriene receptor antagonists have been strongly implicated with AAV and specifically the onset of EGPA [13]; although there is some data which contradicts a putative causal role. These drugs, which include zafirlukast and montelukast, are steroid sparing agents in recalcitrant chronic asthma and so may simply unmask previously undiagnosed disease. Further, case control studies have not only identified relationships between EGPA and anti-leukotrienes but also other common treatments employed to manage difficult asthma. These findings imply that antileucotrienes (and other advanced asthma therapies) may be a surrogate marker of the severity and the gradual worsening of the asthma which typically precedes EGPA onset.

Non-prescribed illicit drugs are also common culprits and not so readily reported by patients. It is therefore important to consider broad urine toxicology screens in the diagnostic work up of a new presentation of vasculitis. The association with cocaine has been best documented, initially as a mimic of ENT limited GPA where its intranasal use has led to ischemic necrosis of the nasal septum and the finding of human neutrophil elastase ANCA [14] and more recently in conjunction with the adulterant levamisole (a cheap anthelmintic agent which resembles cocaine powder and so employed to improve the financial gains of the traders) where a more systemic GPA-like illness, typically involving erosive disease of both the upper airways and the ears, is observed in the context of double-positive MPO and PR3 –ANCA [15].

Finally, although DAV predominantly involve small vessels, a recently reported case series described 9 patients with a medium vessel vasculitis in keeping with polyarteritis nodosa. All had previously received long term therapy with the tetracycline antibiotic minocycline. The phenotypes ranged from cutaneous limited to classical systemic presentations and unusually shared serological evidence of pANCA (mostly directed towards antigens other than MPO).

IN-DEPTH DISCUSSION II

Takayasu's Arteritis

LEARNING OUTCOMES

Takayasu's arteritis (TA) is a rare type of vasculitis that most practising rheumatologists will only meet occasionally during a career.

At the end of this module the student will be able to accurately classify TA, understand the distribution of vascular lesions in TA, conduct appropriate investigations to diagnose and assess the extent of disease involvement, and adequately manage the treatment of patients with immunosuppressive drugs.

Following this module. The student should be able to:

1. Recognise Takayasu's arteritis as a large vessel arteritis and describe it
2. Be aware that it is rare with an incidence of around 1-2/million/year and is most common in Japan
3. Describe the investigation of TA using conventional, computed tomography and magnetic resonance angiography and/or 18 FDG PET scanning
4. Describe the treatment of TA with corticosteroids and the role of other immunosuppressant drugs and surgery

1. BACKGROUND

Takayasu's arteritis is a chronic large vessel vasculitis (granulomatous pan arteritis) which affects predominantly the aorta and its main branches and less frequently the pulmonary arteries. The inflammation of blood vessels generally causes stenosis or occlusion although aneurysms may also develop.

2. HISTORY

The term Takayasu's arteritis was first used by Shinmi in 1939. The first case of TA was described in 1908 by Dr. Mikito Takayasu [1]. He described interesting fundal findings in a 21-year-old girl characterised by circular anastomosis of central retinal arteries.

Onishi and Kagoshima at the same meeting reported similar eye findings in patients whose radial pulses were absent. Although TA has become the most widely used term for this disease, it is also known by different synonyms including, pulseless disease, occlusive thromboangiopathy, middle aortic arch syndrome and Martorell's syndrome.

3. EPIDEMIOLOGY AND PATHOGENESIS

Japanese series have demonstrated a female predominance of 9:1 and TA typically affects young women aged 10 – 30 years (in 70–90% of published series). An international comparative analysis reveals a decline of this female preponderance as one moves westwards from Japan; in Israel the sex ratio is almost equal [2]. The annual incidence in most populations is 1-3/million and it is generally considered to be more common in Asia.

The earliest estimate of the incidence came from the USA (Olmsted County, Minnesota) where three cases were identified during 1971-83 with an estimated annual incidence of 2.6/million [3]. The incidence in Sweden during 1969-75 was estimated to be 0.8/million [4]. In the ethnic Kuwaiti population of Kuwait the incidence between 1989 and 1994 was 2.2/million and 3.3/million in those aged < 40 years. [5]. In Japan, there are estimated to be 150 new cases per annum from a population of 125 million [6], equivalent to an annual incidence of 1-2/million. The prospective Schleswig-Holstein registry recorded an annual incidence during 1998-2002 of 0.5/million [7]. In Lithuania the incidence has been recorded as 1.3/million [8]. Recent data from a UK primary care population suggests that the incidence is 0.45/million in those aged < 40years [9]. These data suggest that the incidence is reasonably uniform across the globe and that there are no major ethnic or time trends. The prevalence of TA in Europe is around 5-7/million [4, 5, 9].

The aetiopathogenesis of TA is unknown. However, reports have suggested a possible association with *Mycobacterium tuberculosis* and other organisms, including spirochetes, bacteria and viruses. Immunological abnormalities including anti-aortic endothelial cell antibodies [10] have been described leading to the hypothesis that it may be a form of autoimmune disease (reviewed in [11]).

It has also been described occasionally associated with other autoimmune disease including juvenile idiopathic arthritis, Still's disease, systemic lupus erythematosus, chronic inflammatory bowel disease and seronegative spondylarthritis. Cellular immune mechanisms may also be involved: one study showed increased numbers of CD8+ (suppressor/cytotoxic) T cells deposited in the inflamed walls of the affected arteries and associated with increased numbers of lymphocytes in the circulation [12].

Subsequent studies have confirmed this association: also increased percentage of high TNF-alpha, low IL-2 producing T cells and also gamma delta T cells are found in patients with active TA compared to inactive TA suggesting an important role for these cells [13, 14].

Two groups have studied an IL-1ra knock out mouse model with enhanced IL-1 signalling. These mice develop inflammation at sites of turbulent blood flow with an infiltrate of monocytes, Th1 cells and dendritic cells [15, 16]. T cells from these mice induce aortitis in nu/nu mice. Suppression of TNF-alpha but not IL-6 prevented development of aortitis, implying that IL-1 and TNF-alpha are key mediators of inflammation in the aorta.

TA has been noted to occur in twins and siblings [17] suggesting that genetic factors may be involved in the pathogenesis, however, only 1% of Japanese TA patients have an affected relative [18]. There are several reports of HLA associations including HLA-DRB1*1502, DPB1*0901, HLA-B*5201, HLA-B*3902 in Japanese patients. HLA-B*5201 appears to be associated with more severe inflammation [reviewed in 19]. In South America the association seems to be with HLA-DRB*1301, HLA-DRB*1602 and DRB*1001.

Pathology

TA is a pan arteritis that typically occurs as focal skip lesions. There is an acute florid inflammatory phase and chronic healed fibrotic phase, both of which may co-exist. During active disease the inflammatory infiltrate is predominantly lymphoblastic with granulomata formation and giant cells involving the media and adventitia. It is characterised by adventitial thickening and cellular infiltration of the tunica media, with local destruction of vascular smooth muscle cells and elastin. The inflammatory lesions originate in the vasa vasorum characterized by perivascular cuffing mainly $\gamma\delta$ T cells, cytotoxic T cells and T helper cells. In the chronic phase, intimal hyperplasia is followed by fibrosis of the tunica media and intima, leading to stenosis [20, 21]. Aneurysm formation may occur following local destruction of the medial layer and an inadequate fibrotic response [21].

4. CLINICAL FEATURES

The presentation of TA is varied and can present with non-specific symptoms depending on which vessels are involved and the stage of the disease. Early reports suggested that TA typically has an early inflammatory phase followed by a late ischaemic/pulseless phase. Some patients do not progress into the occlusive phase and experience a self-limiting monophasic inflammatory episode that does not require chronic immunosuppression. The transition period between the two phases may be over a period of months or years (mean 8 months), although more recent series suggest that these distinct phases are only seen in a minority. Early features include non-specific symptoms of inflammation such as fever, myalgia, arthralgia, weight loss and anaemia. Visual disturbances can be the presenting feature with retinal micro aneurysms, venous dilatation and beading being the most common clinical findings but despite the link to Takayasu's original description serious visual involvement is quite rare. Chronic inflammation of the aorta and its major branches, including the subclavian, common carotid, coronary, pulmonary and renal arteries may result in localized stenosis, vascular occlusion, dilatation and aneurysm formation.

The most common symptoms in Kerr et al's series were therefore related to these findings and included upper extremity claudication, hypertension, pain over the carotid arteries (carotidynia), dizziness and visual symptoms [22]. More than 50% had musculoskeletal symptoms such as myalgia and chest wall pain; synovitis is usually mild.

The most frequent cardiac complication is aortic regurgitation from dilatation of the aortic root. This occurs in approximately 5-55% of patients. Coronary vessel stenosis occurs in up to 25%; other complications include mitral regurgitation, cardiomyopathy and myocarditis. The pulmonary artery may be involved in 50-86% of patients and therefore patients may present with features of pulmonary hypertension. Symptoms such as dizziness, syncope, visual changes, vertigo and arm claudication are more common in studies from Japan and the USA, whereas hypertension is more common in India due to more frequent involvement of the abdominal

aorta and renal artery stenosis. Crescentic glomerulonephritis and acute myocardial infarction have been described. Other rare systemic symptoms include skin lesions (erythema nodosum and pyoderma gangrenosum) and serositis [19].

5. DIAGNOSIS AND INVESTIGATIONS

TA should be considered in the differential diagnosis when any young person presents with large vessel ischaemia and/or hypertension, especially if associated with any systemic symptoms. The diagnosis is often missed or delayed. It is important to note that about 20% of patients are asymptomatic at the time of diagnosis so careful clinical examination is essential looking in particular for bruits over the aorta and its major branches (one third). Reduced or absent pulses of large arteries as well as blood pressure discrepancies of at least 20mm Hg between the arms and/or legs may be seen.

There are no laboratory tests or validated diagnostic criteria for the diagnosis of TA. In contrast to giant cell arteritis, biopsy material is rarely available in patients with TA. Hoffman examined multiple serological tests including ESR, CRP, tissue factor, von Willebrand factor and found that no test reliably distinguished healthy volunteers and patients with TA [23]. Inflammatory markers, such as the ESR and CRP, are raised in 80% of patients with active TA [24]. Patients may have a mild normochromic normocytic anaemia and hyperglobulinaemia but may not have a raised inflammatory response, even in the early inflammatory stages. Complement activity is typically normal and disease specific autoantibodies are characteristically absent. The ACR proposed classification criteria for TA in 1990 and these have remained the most widely applied with three or more of the criteria associated with a sensitivity of 90.5% and specificity of 97.8% [25] (Table 1).

Table 1: ACR Classification criteria for Takayasu's arteritis

Criterion	Definition
1. Age < 40 years old	Development of symptoms or signs related to TA at age < 40 years
2. Claudication of extremities	Development and worsening of fatigue and discomfort in muscles of one or more extremity while in use, especially the upper extremities
3. Decreased brachial arterial pulse	Decreased pulsation of one or both brachial arteries
4. BP difference > 10 mmHg	Difference of > 10mmHG in systolic blood pressure between arms
5. Bruit over subclavian arteries or aorta	Bruit audible on auscultation over one or both subclavian arteries or abdominal aorta
6. Arteriogram abnormality	Arteriographic narrowing or occlusion of the entire aorta, its proximal branches, or large arteries in the proximal upper or lower extremities, not due to atherosclerosis, fibromuscular dysplasia, or similar causes; changes usually focal or segmental.

Note for purposes of classification a patient shall be said to have TA if at least 3 of these 6 criteria are present. The presence of any 3 or more criteria yields a sensitivity of 90.5% and specificity of 97.8%. From Arend et al [25].

Presence of three out of six criteria is required for diagnosis, but by these criteria patients in several Asian countries whose abdominal aorta is predominantly involved would elude diagnosis. Although ophthalmological findings and/or symptoms are excluded, in Japan approximately 35 per cent of patients show abnormal ophthalmological findings including micro aneurysm, retinal haemorrhage, cataract, or glaucoma.

6. DISEASE MONITORING

The critical limitation in managing a patient with TA has been the inability to accurately assess disease activity. Analysis of acute phase response is often an unreliable indicator of disease activity. Specific activity scores and outcome measures have been developed for TA [26].

7. CLINICAL IMAGING

Conventional angiography

Conventional angiography has been the gold standard investigation for the diagnosis of TA. The commonest angiographic findings are long, smooth vascular stenoses and occlusions, and sometimes aneurysms.

Panangiography is required to determine the extent of disease involvement [21]. Diffuse disease affecting the aorta and its branches above and below the diaphragm is the most common pattern of disease worldwide. (Figures 8, 9 and 10)

However, conventional angiography cannot demonstrate earlier vasculitic changes such as thickening of the vessel wall and mural enhancement, and is thus not useful for early diagnosis. Disadvantages of conventional angiography include its invasive nature and the exposition to ionizing radiation. Furthermore it is contraindicated in patients with impaired renal function and in those allergic to iodine. Hence, other modalities of imaging have been explored in recent years including ultrasound, CT, magnetic resonance imaging and 18F-fluorodeoxyglucose positron emission tomography (18F-FDG-PET). For all these reasons, conventional angiography has become a therapeutic procedure for endovascular intervention rather than a diagnostic method [21].

*Figure 8 - Classification of Takayasu's Arteritis***Table 19.1** Classification of Takayasu's arteritis

Type	Site of involvement
I	Branches of aortic arch
IIa	Ascending aorta, aortic arch and its branches
IIb	Ascending aorta, aortic arch and its branches and thoracic descending aorta,
III	Thoracic descending aorta, abdominal aorta and/or renal arteries,
IV	Abdominal aorta and/or renal arteries.
V	Combination of Types IIb and IV

Figure 9 - Diagrammatic representation of the different types of Takayasu's Arteritis

© www.rheumtext.com - Hochberg et al (eds)

Figure 10 - Angiogram showing narrowing of lower aorta and marked narrowing of common iliac arteries in a young lady with TA

Magnetic Resonance Imaging (MRI)

MRI is particularly indicated to examine the aorta and the other deep, large vessels without the use of ionizing radiation or iodinated contrast. Increased vessel wall thickness (usually with a diffuse circumferential pattern), associated with vessel wall oedema on T2 and fat-suppressed sequences, and mural contrast enhancement on T1 sequences are early signs of vascular inflammation. Moreover, MRI angiography (MRA) provides luminal information, such as arterial stenosis, occlusion and dilatation [21]. Comparative studies with conventional angiography are encouraging. The potential for MRI to assess disease activity and response to treatment needs to be further explored. Serial assessment of mural thickness may provide evidence of response to treatment. Limitations of MRI/MRA include poor visualization of calcifications and falsely accentuated stenoses. Disadvantages include high cost of the procedure and long acquisition time. Furthermore it is contraindicated in patients with impaired renal function, claustrophobia and in those with some metal devices [21].

High Resolution Doppler Ultrasound

High resolution ultrasound (US) has been reported to be up to 10 fold more sensitive than MR for the assessment of superficial arteries such as the common carotid arteries [27]. Increasingly it is being used to assess involvement in large branches of the aorta. The high resolution of US raise the possibility that it may offer a means by which disease activity and response to treatment may be monitored, but this has yet to be studied. The procedure is also highly operator dependant and requires operators with vascular expertise [21].

CT Angiography

Computed tomography (CT) and CT angiography (CTA) are well suited to detect inflammatory changes in large arteries because of their good spatial resolution and convenient scanning time. CT can measure aortic diameter and detect mural calcifications. CTA can evaluate both the vessel wall and the lumen of the large vessels. CTA has a role in diagnosing early and advanced TA. In early TA, CT may show arterial wall thickening with mural enhancement and low-attenuation ring on delayed images. In late TA the arterial wall is slightly thickened with high attenuation or calcifications. Furthermore CTA may show TA complications such as arterial stenosis, occlusion and dilatation. The role of CTA in monitoring disease activity in TA patients is still unclear. The main disadvantage of CT/CTA is the exposure to a significant amount of ionizing radiation, which limits its repeated use. Furthermore it is contraindicated in patients with impaired renal function and in those allergic to iodine. [21].

¹⁸F-Fluorodeoxyglucose Positron Emission Tomography

¹⁸F-Fluorodeoxyglucose (FDG) positron emission tomography (PET) is a nuclear medicine technique, currently often co-registered with computerized tomography (CT; PET/CT), which assesses the extent and amount of vascular uptake of the radiolabelled glucose analogue FDG by metabolically active cells in infections,

malignancies, and inflammation. In active TA, there is increased FDG uptake by the vessel wall, typically with a smooth linear pattern. PET is able to visualize virtually all vessels larger than 4mm in diameter, but not arteries of smaller calibre such as the renal arteries [21]. Principal advantage of PET is its ability to identify pre-stenotic disease in patients presenting with non-specific symptoms in the early phase of the disease [28-33]. As yet 18F-FDG-PET scanning has only been shown to be of use in the diagnosis of TA. In a recent systematic review and meta-analysis, PET had a sensitivity of 87% and a specificity of 73% for TA [34]. Prospective studies are required to confirm its utility as a tool for assessment of disease activity and for monitoring. Its major limitation is that involves radiation exposure, especially when combined with CT and this limits its serial use. In addition it is expensive and because the isotope has a short half-life its use is limited to a few centres (Fig 11).

Figure 11 - 18F-Fluorodeoxyglucose positron emission tomography (18F-FDG-PET) showing increased uptake in the aorta, subclavian arteries and mesenteric vasculature.

8. MANAGEMENT

The current treatment modalities include glucocorticoids, immunosuppressive therapy and non-medical intervention. There is limited data on which to build an evidenced based approach to the management of TA. EULAR have recently published guidelines on the management of large vessel vasculitis [35].

Glucocorticoids are the mainstay of medical treatment. Improvement /resolution of systemic symptoms has been reported in 25-100% of glucocorticoid treated patients. The optimal dosage has not been clearly defined. There have been no comparative trials to determine the optimal dosage or length of treatment. An initial dose of prednisone 1 mg/Kg/day (maximum 60 mg/day) is recommended in all newly-diagnosed, active TA patients. Initial high-dose GC should be maintained for a month, and then tapered gradually. This starting dose may be lowered in selected individuals at high risk of steroid toxicity. Because around 20% of patients have a self-limited, monophasic inflammatory episode, the systematic prescription of an immunosuppressive agent for all newly-diagnosed TA patients is not essential. If a relapse occurs, treatment with glucocorticoids at the higher previously effective dose is recommended, and adjunctive immunosuppressive agents should be considered [36]. There is not the degree of evidence for the use of immunosuppressive therapies in TA as there is for the ANCA associated vasculitides. Methotrexate is now the first choice second line therapy based largely on small open labelled studies and anecdotal evidence [22, 36-37]. Azathioprine remains a suitable alternative to MTX in TA [36]. Before the widespread use of MTX, cyclophosphamide (CYC) was the agent of choice for corticosteroid-resistant TA. CYC is now largely reserved for life threatening disease or disease unresponsive to synthetic and biological immunosuppressive agents. Mycophenolate has shown some promise as an alternative to MTX in TA [36].

Observational evidence supports the use of anti-TNF- α agents in TA patients with relapsing disease. Infliximab is the most commonly reported anti-TNF agent used. However, anti-TNF- α are not curative, and relapses remain common [36, 38-39]. Preliminary experience with the use of the IL-6 receptors inhibitor monoclonal antibody tocilizumab in TA suggests safety and clinical and radiographic efficacy [36, 38-40]. Both anti-TNF- α agents and TCZ seem equally effective and safe in TA patients with relapsing disease [39]. In case of a relapse under biological therapy, a switch to another biologic agent should be considered [36, 38-39]. Large RCTs are required to generate convincing evidence of efficacy for both anti-TNF- α and anti-IL-6 (-receptor) therapies in TA.

The first multicentre randomized clinical trial in TA has recently been completed. This trial evaluated the efficacy of abatacept in the treatment of TA. The primary endpoint was duration of remission (relapse-free survival, RFS). The RFS at 12 months was estimated to be 22% for those receiving abatacept and 40% for those receiving placebo ($p = 0.853$). In this study, the addition of abatacept to prednisone did not reduce the risk of relapse in patients with TA [41].

As with all chronic rheumatologic conditions there is an increased risk of developing premature atherosclerosis. Cardiovascular risk assessment should be made with careful attention to and treatment of hypertension. Consideration of surgical intervention into renal artery stenosis should be made. Lifestyle factors should be addressed including smoking and dietary habits. All patients should be evaluated for aspirin and a statin prescription unless contraindicated. Osteoporosis is a recognized consequence of high dose and /or prolonged treatment with corticosteroids and prophylaxis should be considered in all patients on treatment for TA [36].

Surgical treatment

Surgical treatment is beneficial in selected cases. Surgery should be performed if possible, when inflammation is quiescent, as aneurysm, graft dehiscence or graft occlusion is more likely in the presence of active arteritis. However surgery to prevent imminent ischaemia of a vital organ should not be delayed because of active inflammation. The operative procedures include bypass of stenosed segments of arteries, resection of aneurysms and replacement of aortic valves. Angioplasty and/or stenting can be effective procedures for some vascular complications of TA, especially for coronary atherosclerosis and renal artery stenosis. [42]

Prognosis

Earlier diagnosis and initiation of treatment has greatly improved the outcome in patients with TA. Non-invasive diagnostic imaging that can enable the assessment of disease activity and hence allow adjustment of treatment accordingly will improve our understanding and management of the disease. However the outcome of patients with TA varies greatly and the most common causes of mortality are congestive cardiac failure, cerebrovascular events, myocardial infarction, aneurysm rupture and renal disease.

Predictors of poor outcome are progressive disease, TA retinopathy, secondary hypertension, aortic valve insufficiency or aneurysms [43]. Overall survival rates of 82.9% at 15 years have been reported from Japan [44]; and Park et al from Korea reported 10 year survival of 87.2% [45]. In a recent US series the overall survival was 97% at 10 years and 86% at 15 years. Mortality was increased compared with the general population (standardized mortality ratio, 3.0; 95% CI, 1.0-8.9) [46]. Mortality directly related to TA usually occurs from congestive cardiac failure, cerebrovascular events, myocardial infarction, aneurysm rupture or renal failure.

Anca-associated vasculitides and polyarteritis nodosa

Xavier Puéchal, Michele Iudici, Cristina Ponte

A previous version was coauthored by Raashid Luqmani, Christian Pagnoux and Cristina Ponte

LEARNING OBJECTIVES

- Precisely locate polyarteritis nodosa (PAN) and antineutrophil cytoplasmic autoantibodies (ANCA)-associated vasculitides in the current definitions of primary systemic vasculitides
- Conduct appropriate investigations to diagnose and evaluate the severity of PAN and ANCA-associated vasculitides
- Adequately manage the treatment of patients with a newly diagnosed form of each of these vasculitides in their more usual presentations
- List the different primary necrotising vasculitides of small vessels, according to the revised Chapel Hill nomenclature, and among them, the ANCA-associated vasculitides, using their recently revised names
- Describe and explain the different clinical phenotypes of granulomatosis with polyangiitis (GPA) (Wegener's) and their respective association with cytoplasmic ANCA positivity with proteinase 3 specificity
- Recognise that microscopic polyangiitis (MPA) has been clearly distinguished from PAN especially since the publication in 1994 of the Chapel Hill criteria and that it is often associated with perinuclear ANCA (pANCA) to myeloperoxidase (MPO)
- Explain that only anti-MPO pANCA have clearly been proved to be pathogenic in animal models and in a single case report of their transplacental transfer resulting in pulmonary-renal syndrome of a new born human infant. However, despite these latter findings and other recent studies, the precise origin and mechanisms leading to the production of ANCA remain undetermined

- Describe the other pathogenic mechanisms that may be involved in ANCA-associated vasculitides, including specific T lymphocyte subsets or dendritic cell dysfunction
- Describe and explain the general lines of treatment for GPA (Wegener's) and MPA—that is, induction therapy followed by a maintenance regimen. Know that the optimal duration of maintenance regimens remains to be determined and that, despite such treatment, the relapse rate remains high
- Evaluate the place of biological agents in the therapeutic armamentarium for patients with GPA (Wegener's) or MPA. Especially, outline the results of recent therapeutic studies using targeted monoclonal B cell therapy—that is, rituximab, which was shown to be non inferior to conventional first-line cyclophosphamide-based induction therapy in patients with active generalised GPA (Wegener's) or MPA, and superior to AZA as maintenance therapy.
- Differentiate eosinophilic GPA (Churg–Strauss syndrome) (EGPA) from the other ANCA-associated vasculitides, based on their clinical and biological manifestations
- Explain that EGPA is associated with pANCA to anti-MPO in 30–40% of patients, and that there are some clinical differences according to their presence or not, suggesting that distinct pathogenic mechanisms may be involved, such as ANCA- and/or eosinophil-mediated cytotoxicity
- Define the treatment for patients with EGPA according to the Five-Factor Score (FFS)
- Describe the overall outcome of patients with EGPA, especially their frequent glucocorticoid dependence
- Recognise that the identification of predictive parameters of relapse might in the future allow adjustment of treatment according to individual patient characteristics. Notably, several studies showed that ANCA increases were not reliable as predictors for relapse, demonstrating that ANCA levels cannot be used to guide immunosuppressive therapy
- Recognise PAN as one of the two medium vessel systemic necrotising vasculitides and describe its main clinical features
- Describe the correct treatment for patients with PAN, especially according to their hepatitis B virus status and the presence or not of poor prognostic factors, according to the FFS
- Recall the global outcome and relapse rate of PAN
- Explain that the original prognostic FFS (1996) can be used to assess the severity of PAN, MPA and EGPA, and that the revised FFS (2010) can now also be applied to patients with GPA (Wegener's)
- Explain that PAN, GPA (Wegener's), MPA and EGPA activity can be evaluated during clinical trials using the Birmingham Vasculitis Activity Score (BVAS) version 3, and know that for patients with GPA (Wegener's) there is a specific GPA-BVAS

1 Background knowledge

For this chapter, readers should be aware of the classification and consensus definitions of the primary necrotising vasculitides, mainly the revised Chapel Hill nomenclature, and the recent changes in the names for some of them. Polyarteritis nodosa (PAN) is a medium vessel vasculitis, whereas granulomatosis with polyangiitis (GPA) (Wegener's), microscopic polyangiitis (MPA) and eosinophilic GPA (EGPA, Churg–Strauss) are small vessel vasculitides. Because the last three are often associated with antineutrophil cytoplasmic antibodies (ANCA), they have been grouped under the label of ANCA-associated vasculitides. However, they differ in many clinical and biological aspects and their treatment is also slightly different. No personal experience of these vasculitides is required because the main clinical features of these diseases are described in-depth in this module. However, experience with glucocorticoid and immunosuppressive therapies is necessary to understand their potential benefits and risks for the vasculitides.

Even though the incidence of ANCA-associated vasculitides has substantially increased during the past 10 years for several reasons, including better awareness of these diseases, they remain uncommon, with less than 30 new cases per million population each year. It is therefore probable that every rheumatologist will be confronted at least once in his/her life with an affected patient. The incidence of PAN has decreased over the past decades, along with that of hepatitis B virus (HBV) infection, but cutaneous polyarteritis remains common.

2 Introduction

Systemic vasculitides are a heterogeneous group of diseases characterised by inflammation of vessel walls. They are defined according to the Chapel Hill nomenclature, published in 1994 and revised in 2012 (box 1), which is mainly based on the calibre of the predominantly affected vessels (Jennette et al, 1994; Jennette et al, 2013*). The group of large vessel vasculitides includes giant cell arteritis and Takayasu's disease, while medium vessel vasculitides include Kawasaki disease and PAN. The small vessel vasculitides are divided into two categories, depending on the presence of immune deposits: immune complex small vessel vasculitis and ANCA-associated vasculitis (AAV). The first category, characterised by moderate to marked vessel wall deposits of immunoglobulin and/or complement, is represented by anti-glomerular basement membrane disease, cryoglobulinaemic vasculitis, hypocomplementaemic urticarial vasculitis (anti-C1q vasculitis) and IgA vasculitis (Henoch–Schönlein). By contrast, AAV has few or no immune deposits and is associated with the presence of ANCA specific for myeloperoxidase (MPO-ANCA) or proteinase 3 (PR3-ANCA). Depending on their clinical presentation and ANCA specificity, AAV is divided into three major variants: GPA (Wegener's), MPA and EGPA (Churg–Strauss).

Box 1 2012 Revised International Chapel Hill nomenclature of vasculitides**Large vessel vasculitis**

- Takayasu arteritis
- Giant cell arteritis

Medium vessel vasculitis

- Polyarteritis nodosa
- Kawasaki disease

Small vessel vasculitis**ANCA-associated vasculitis**

- Microscopic polyangiitis
- Granulomatosis with polyangiitis (Wegener's)
- Eosinophilic granulomatosis with polyangiitis (Churg–Strauss)

Immune complex

- Anti-GBM disease (Goodpasture's)
- Cryoglobulinaemic vasculitis
- IgA vasculitis (Henoch–Schönlein)
- Hypocomplementaemic urticarial vasculitis (anti-C1q vasculitis)

Variable vessel vasculitis

- Behçet's disease
- Cogan's syndrome

Single organ vasculitis

- Cutaneous leucocytoclastic angiitis
- Cutaneous arteritis
- Primary CNS vasculitis
- Isolated aortitis
- Others

Vasculitis associated with systemic disease

- Lupus vasculitis
- Rheumatoid vasculitis
- Sarcoid vasculitis
- Others

Vasculitis associated with probable aetiology

- Hepatitis C virus-associated cryoglobulinaemic vasculitis
- Hepatitis B virus-associated vasculitis
- Syphilis-associated aortitis
- Drug-associated immune complex vasculitis
- Drug-associated AAV
- Cancer-associated vasculitis
- Others

AAV, ANCA-associated vasculitis; ANCA, antineutrophil cytoplasmic antibody; CNS, central nervous system; GBM, glomerular basement membrane.

Adapted from Jennette et al, *Arthritis Rheum* 2013;65:1–11*.

PAN, GPA, EGPA and MPA (as well as other vasculitides such as Kawasaki disease) are classically (but not universally, because of the segmental distribution of the lesions) associated with fibrinoid necrosis of the arterial wall on histology; therefore they are often termed necrotising systemic vasculitides.

3 ANCA-associated vasculitides

3.1 Granulomatosis with polyangiitis (Wegener's)

3.1.1 Classification

GPA, formerly known as Wegener's granulomatosis or disease, was first described in 1931 by Klinger, with the clinical and pathological unique features added to the description in 1936 by Wegener. The disease is characterised by granulomatous necrotising inflammatory lesions of the upper and/or lower respiratory tract, often associated with pauci-immune glomerulonephritis, which in some cases can progress rapidly, resulting in significant loss of renal function. In 1990, the American College of Rheumatology (ACR) proposed four classification criteria for GPA in patients with documented vasculitis, with two being necessary to classify the patient with 88.2% sensitivity and 92.0% specificity (Leavitt et al, 1990).

3.1.2 Epidemiology

The reported incidence of GPA varies from 2 to 12 per million population and the prevalence from 24 to 157 per million people (Lane et al, 2005; Mohammad et al, 2009). There is some geographical variation, GPA being more frequent in northern rather than southern European countries. There appears to be variation in incidence over time, with spikes seen every 6–8 years, at least in the UK, especially for PR3-ANCA-associated GPA (annual incidence rising to 17.4/million/year in 1996–8 and in 2005–7, as compared with only 4.5/million/year between these periods) (Watts et al, 2011). Ethnicity may also be a factor because GPA is rarely seen in African Americans in comparison with whites (Cao et al, 2011). In addition, the annual incidence of GPA in Japan is only 2.1 per million people, compared with MPA at 18.2 per million people, and case series from China also suggest a lower incidence of GPA than MPA. There is no gender predominance in GPA and the peak incidence is in the fourth through sixth decades of life; by contrast, it is very much less common in children and adolescents (Lynch and Tazelaar, 2011).

Epidemiological studies have shown that exposure to some environmental agents such as silica, dust, cattle, hard metals or organic solvents was noted before diagnosis in some patients with GPA but these represented <10% of all cases (Lane et al, 2005).

3.1.3 Clinical manifestations

Clinical manifestations of GPA are summarised in table 1.

Table 1 Frequencies of organ/system involvement or manifestations at diagnosis of granulomatosis with polyangiitis (Wegener's)

Study	Patients (N)	Organ/system involved or manifestation (%)							
		ENT	Lung	Kidney	Heart	GI	Skin	CNS	PNS
Koldingsnes <i>et al</i> , 2003	56	80	61	80	20	5	34	13	23
Fauci <i>et al</i> , 1983	85	91	94	85	12	–	45	–	–
Reinhold-Keller <i>et al</i> , 2000	155	93.5	55	53.5	12.9	–	23.2	–	20.6
Hoffman <i>et al</i> , 1992	158	92	85	72	6	–	46	8	15
Stone, 2003	180	77	60	54	1.7	1.7	20	8.9	
Anderson <i>et al</i> , 1992	265	75	63	60	<4	–	25	–	–
Holle <i>et al</i> , 2010	445	91–98	52–67	44–54	6–24	1–8	20–32	10–12	39–41

CNS, central nervous system; ENT, ear, nose and throat; GI, gastrointestinal; PNS, peripheral nervous system.

3.1.3.1 General symptoms

Constitutional symptoms such as fever, weight loss and fatigue may occur at presentation or during the disease course in 30–80% of patients.

3.1.3.2 Musculoskeletal symptoms

Musculoskeletal symptoms are common, with non-erosive polyarthritis affecting medium- and large-size joints in two-thirds of patients (Lynch and Tazelaar, 2011).

3.1.3.3 Upper airway involvement

Granulomatous ear, nose and throat (ENT) lesions are the most typical manifestations of the disease, noted in more than three-quarters of patients at diagnosis, with crusting rhinitis, sinusitis, chronic otitis media, saddle-nose deformity (figure 1) and/or nasal septum perforation.

Hearing loss may occur (conductive and sensorineural) owing to inflammation of middle ear mucosa, dysfunction of the Eustachian tube or cochlear artery vasculitis. Oral manifestations are uncommon and may present as ulcerative stomatitis or hyperplastic gingivitis, 'Strawberry gingival hyperplasia' (figure 2). Laryngeal involvement can cause hoarseness and lead to subglottic stenosis in up to 15% of cases (Hoffman *et al*, 1992).

Figure 1 Saddle-nose deformity in a patient with granulomatosis with polyangiitis (Wegener's).

Figure 2 Localised hypertrophic and painful gingivitis (or strawberry-like gum) in a patient with granulomatosis with polyangiitis (Wegener's).

3.1.3.4 Pulmonary involvement

Two-thirds of patients have pulmonary involvement, with bilateral parenchymal nodules, cavitated in half of the cases (figures 3–8), and/or alveolar haemorrhage (figures 9-10) in 10–20% of patients being the more characteristic manifestations.

Figure 3 Lung nodule in a patient with granulomatosis with polyangiitis (Wegener's).

Figure 4 Lung nodule in a patient with granulomatosis with polyangiitis (Wegener's).

Figure 5 Apical lung nodules in a patient with granulomatosis with polyangiitis (Wegener's) (surrounded by some ground glass infiltrates).

Figure 6 Peripheral lung nodule with surrounding inflammation and ground glass opacity, suggestive of perilesional haemorrhage, in a patient with granulomatosis with polyangiitis (Wegener's).

Figure 7 Lung nodules in a patient with granulomatosis with polyangiitis (Wegener's), including a large cavitated nodule.

Figure 8 Cavitated lung nodule in a patient with granulomatosis with polyangiitis (Wegener's).

Figure 9 Bilateral lung infiltrate due to alveolar haemorrhage in a patient with granulomatosis with polyangiitis (Wegener's).

Figure 10 Bilateral lung infiltrate due to alveolar haemorrhage in the same patient with granulomatosis with polyangiitis (Wegener's).

3.1.3.5 Renal involvement

Rapidly progressive glomerulonephritis, also called necrotising crescentic glomerulonephritis or pauci-immune glomerulonephritis, is the third main manifestation of GPA, noted in 40–100% of patients depending on the series (i.e., more commonly in nephrology versus rheumatology series).

3.1.3.6 Neurological involvement

Peripheral nervous system involvement occurs in one-third of patients, mainly represented by mononeuritis multiplex (79% of the patients with peripheral neuropathy), then sensorimotor polyneuropathy. Central nervous system (CNS) involvement is less common and can be seen in 6–13% of patients, usually later in the course of the disease. Initial presentation with pachymeningitis is one of the described CNS manifestations, which is suggestive, but not specific, for GPA (figure 11).

Figure 11 Pachymeningitis in a patient with granulomatosis with polyangiitis (Wegener's). Note the thickened meninges with increased brightness (gadolinium-enhanced T1 sequence).

3.1.3.7 Skin lesions

Skin lesions occur in 10–50% of patients, with palpable purpura of the legs and feet being the most common manifestation. Necrotic papules on the extensor surfaces of the limbs, nodules or extensive and painful cutaneous ulcerations are less common but suggestive of the disease (figures 12–14).

Figure 12 Necrotic and purpuric skin lesions in a patient with granulomatosis with polyangiitis (Wegener's).

Figure 13 Maculopapular, purpuric and necrotic skin lesions in a patient with granulomatosis with polyangiitis (Wegener's).

Figure 14 Distal ischaemic lesions of the fingers in a patient with granulomatosis with polyangiitis (Wegener's).

3.1.3.8 Other clinical manifestations

Eye involvement, mainly episcleritis, is also frequent in GPA. Orbital granuloma or pseudo-tumour (which constitutes 15% of the eye involvement) may compress important muscles or nerves (figures 15 and 16). Gastrointestinal involvement is uncommon (usually detected in autopsy studies) (Deniz et al, 2007) and cardiac manifestations are reported with a frequency varying from 0% to 12%.

Figure 15 Left posterior intraorbital (intraconic) granulomatous pseudo-tumour in a patient with granulomatosis with polyangiitis (Wegener's); the patient's left eye had to be surgically removed because of painful ocular compression and ischaemia (horizontal MR image).

Figure 16 Left posterior intraorbital granulomatous pseudo-tumour in a patient with granulomatosis with polyangiitis (Wegener's); the patient's left eye had to be surgically removed because of painful ocular compression and ischaemia (parasagittal MR image).

Some studies have highlighted the higher risk of venous thrombosis in patients with GPA (as well as in MPA and EGPA, but not PAN) during the active phases of the disease. Indeed, the incidence rate of venous thromboses was 7 per 100 patients/year, as compared with 0.3 per 100 patients/year in the general population; this finding would justify closer monitoring of the patients for those events but could not be used to justify systematic prophylaxis with anticoagulation for all patients (Merkel et al, 2005; Stassen et al, 2008; Allenbach et al, 2009).

3.1.4 Phenotypes of GPA

Although to date their precise definitions are not widely accepted, at least two different forms of GPA may be distinguished: systemic/generalised/severe forms and localised/limited/early-systemic forms (Hoffman et al, 1992; Merkel et al, 2005). Systemic GPA is represented by kidney involvement, alveolar haemorrhage, involvement of one or more other vital organ(s) or less severe manifestation(s) but with significant general systemic symptoms, such as fever and/or weight loss. Limited disease corresponds to GPA whose manifestations remain limited mostly to the upper respiratory tract or, more rarely, skin (i.e., not life or major organ threatening manifestations). Notably, these forms seem also to differ histologically, with systemic GPA being associated more often with predominantly vasculitic lesions and localised GPA with marked granulomatous features (Godman and Churg, 1954), possibly because of a more central role of Th2 T lymphocytes in the former and Th1 T lymphocytes in the latter. In addition, whereas 90% of patients with

systemic GPA have cytoplasmic ANCA (cANCA), with a diffuse cytoplasmic pattern on immunofluorescence assay and directed towards PR3 on enzyme-linked immunosorbent assay (ELISA), only 50–80% of those with limited GPA are ANCA positive.

These limited/localised forms represent less than one-third of all GPA cases at diagnosis and especially occur in women, and at a slightly younger age than in those with systemic GPA (Stone, 2003). However, most of them will evolve over time to a more systemic form and patients with persistently and strictly localised GPA are thus rare and represent <5% of all patients with GPA (Holle et al, 2010; Pagnoux et al, 2011). Conversely, once life-threatening manifestations have been treated and controlled, systemic GPA can further evolve as a localised but often persistent form, as evidenced by crusting rhinitis or subglottic stenosis.

3.1.5 Histology

In some patients, the combination of highly suggestive clinical features and the detection of anti-PR3 cANCA can be sufficient to make the diagnosis of GPA and begin treatment. However, histological confirmation of the diagnosis is preferred and it should be performed when there is a suspicion of kidney involvement. It has a prognostic value for renal recovery (Lind van Wijngaarden et al, 2006; Berden et al, 2010). In addition, renal biopsy can also be important to exclude other causes of renal problems, such as drug toxicity.

Nasal and/or sinus biopsy is easy to perform, but only 20% and 50% of such biopsies, respectively, contribute to diagnosis (Devaney et al, 1990; Duna et al, 1995). Cutaneous biopsy often shows small vessel leucocytoclastic vasculitis, which is non-specific. Skin nodules are rare in GPA but can coincide with necrotising or granulomatous vasculitis of medium arterioles or, most often, extravascular granulomas. Bronchoscopy with examination of bronchoalveolar fluid can confirm alveolar haemorrhage, when present, but also, and, more importantly, rule out and/or diagnose associated infection, when suspected. Bronchial biopsy can reveal granulomatous inflammation in a maximum of 25% of cases, but rarely shows vasculitis. Surgical biopsy of lung nodules more often contributes to diagnosis, showing necrotising vasculitis in up to 60% of cases, sometimes in association with vascular or extravascular granuloma, but can sometimes be feasible only with open-lung surgery. In cases of alveolar haemorrhage, lung biopsy may show diffuse alveolar infiltrate and haemorrhage, with varying degrees of necrotising capillaritis and some granulomatous inflammation. Tracheal biopsy in cases of subglottic lesions with stenosis can be dangerous and contributes to diagnosis in less than a quarter of cases. Neuromuscular biopsy, especially of the peroneal muscle and nerve branches, has a diagnostic sensitivity of 60% in patients with clinically diagnosed peripheral nerve involvement (figure 17), but can lead to definitive sensory deficit at the site of the biopsy.

Figure 17 Vasculitis of a small branch of a larger and normal artery on a neuromuscular biopsy sample from a patient with granulomatosis with polyangiitis (Wegener's).

3.1.6 Pathogenesis of GPA

The aetiology and pathogenesis of GPA remain unknown, but as in many other autoimmune conditions, appear to be multifactorial, involving the interaction between a genetically predisposed host, environmental factors and a breakdown of immune tolerance (Jennette and Falk, 2013).

Studies have shown a genetic predisposition in GPA. It has been confirmed that multiple HLA genes are prevalent in different AAV populations, with HLA-DPB1 being over-represented in patients with GPA (Heckmann et al, 2008). In addition, a genome-wide association study has provided evidence for the association of PR3-ANCA disease and SERPINA1 and PRTN3. SERPINA1 encodes α -1 antitrypsin, a serine protease which has PR3 as one of its substrates, and PRTN3 encodes PR3 (Lyons et al, 2012).

A pathogenic role for ANCA has been supported by several in vitro and in vivo animal models. However, unlike MPO-ANCA disease, a robust animal model of PR3-ANCA disease has not yet been developed. PR3 is a 29 kDa neutrophil serine protease encoded by a single gene located on chromosome 19p13.3. This protein is mainly stored in primary granules of human neutrophils and monocytes, but is also present at the cell membrane surface, with genetic regulation of its expression. Following tumour necrosis factor α priming, the ANCA-target antigen expression on the neutrophil membrane surface increases owing to membrane flip-flop with externalisation of the inner membrane-bound PR3, as well as the exocytosis of granule contents, making PR3

more accessible for interaction with ANCA. ANCA thereafter promote neutrophil adhesion to endothelial cells and their lysis. ANCA can also activate monocytes, which results in enhanced production of reactive oxygen species (Jennette et al, 2011a*; Kallenberg, 2011).

Pertinently, in GPA, higher levels of membrane-bound PR3 expression have been demonstrated as a result of its flip-flop following neutrophil activation, which involves interactions with phospholipid scramblase 1 and may interfere with macrophage clearance of apoptotic neutrophils (Kantari et al, 2005). However, the primary mechanisms leading to the synthesis of ANCA and to the shift from natural to pathogenic autoantibodies and, eventually, the mechanisms leading to the formation of granulomas in GPA are not clearly understood. Passive transfer of anti-PR3-ANCA in animal models has been demonstrated relatively little so far, requiring additional costimulation(s) or very specific genetic backgrounds to observe any inflammation or limited vasculitis, with no or almost no granuloma (Pfister et al, 2004*; Primo et al, 2010). Pendergraft et al showed that immunisation with the middle region of the protein derived from the antisense DNA strand of PR3 (cPR3) resulted (in a mouse model) in the production of antibodies not only to cPR3 but also to PR3, which are bound to each other, indicating idiotypic relationships (Pendergraft et al, 2004). The authors suggested, by comparing protein gene sequences, that these anti-cPR3 antibodies might be produced in vivo as a response to various microbial challenges, such as *Staphylococcus aureus*, that would cross-react with the autoantigen (cPR3). In vitro, PR3 can induce the maturation of dendritic cells via the protease-activated receptor-2 pathway (Csernok et al, 2006). These dendritic cells thereby become fully competent antigen-presenting cells and can induce stimulation of specific CD4 T cells, which produce interferon γ , as a Th1-like autoimmune response, potentially favouring granuloma formation.

In addition, Abdulahad et al demonstrated that patients with remitting GPA had an expanded proportion of regulatory T cells, a subset of CD4 T cells that express CD25 (high) and FoxP3, but are functionally defective, potentially further leading to the persistence of the autoimmune response (Abdulahad et al, 2007). Recently, PR3 has been shown to induce platelet shape change, but not aggregation, adding another mechanism to the complex interaction between neutrophils and platelets (Peng et al, 2014).

In addition, PR3 expressed on apoptotic neutrophils impairs resolution of inflammation by interfering with phagocytosis of these cells by macrophages. Recent data have shown how PR3 may disrupt immune silencing associated with clearance of apoptotic neutrophils (Millet et al, 2015). The membrane-bound PR3 perpetuates inflammation through macrophage polarization and effects on plasmacytoid dendritic cell (pDC)–T-cell interactions, suggesting that PR3 expressed on the membrane of apoptotic cells acts as a ‘danger’ signal, and that PR3-ANCA-associated vasculitis might be considered not only as an autoimmune disease, but also as a nonresolving autoinflammatory disease.

Finally, other pathogenic mechanisms or autoantibodies may also be involved in GPA. Some patients with GPA (5%) have perinuclear-labelling pANCA with anti-myeloperoxidase (MPO) specificity, preferentially seen in MPA, rather than anti-PR3 cANCA (the distinction between GPA and MPA can be difficult in those cases). In addition, antibodies against lysosomal membrane protein 2 (LAMP-2) have been reported in AAV, with a prevalence of up to 90% in untreated patients at presentation (Kain et al, 2008; Kain et al, 2012). However, there are still insufficient data about their pathogenicity. Kain et al reported that the immunisation of rats with anti-LAMP-2 induced focal necrotising glomerulonephritis, but no other group has been able to reproduce these results so far (Roth et al, 2012). In these studies anti-LAMP-2 antibodies were generated after immunisation with FimH, a bacterial adhesion of common Gram-negative fimbriated bacteria, such as *Escherichia coli*. This cross-reactivity between FimH and LAMP-2 raises the question as to whether natural infection with fimbriated bacteria might induce AAV. In favour of this hypothesis Kain et al reported that nine of 13 consecutive patients presenting with AAV had had a microbiologically proven infection with a fimbriated organism within the preceding 3 months; and Roth et al reported that 12% of a sample of 105 patients with urinary tract infections had positive assays for LAMP-2 in their ELISA. Currently, the INTRICATE Consortium (<http://www.intricate.eu/>) is conducting a multicentre prospective observational study to determine whether infections with type 1 fimbriated bacteria induce antibodies to LAMP-2 in man, and to study their possible association with AAV (Kain, 2013).

3.2 Microscopic polyangiitis

3.2.1 Classification criteria

MPA did not appear in the classification criteria established in 1990 by the ACR. PAN and MPA were then thought to be different forms of the same disease because some clinical manifestations are very similar and MPA was thus initially considered to be a 'microscopic' form of PAN. MPA was unanimously recognised in the mid-1990s, with the Chapel Hill nomenclature, as a clearly different entity among systemic vasculitides (Jennette et al, 1994). The discovery of ANCA (van der Woude, 1985), which are only present in some small vessel vasculitides and not in PAN, further supported the distinction between MPA and PAN.

3.2.2 Epidemiology

Like all other vasculitides, MPA is a rare disease. Because PAN and MPA have long been grouped together in published studies, valid epidemiological data are sparse and only the more recent studies can be considered reliable for MPA frequencies.

MPA has been reported worldwide and can affect all racial groups, but with a predominance in Caucasians. Men are affected slightly more often, with the male to female ratio ranging from 1.1 to 1.8. The average age at

onset is about 50 years. The total annual incidence is estimated at 3–24 per million population, and the prevalence at 25–94 per million population (Mohammad et al, 2007; Mohammad et al, 2009).

3.2.3 Clinical features

The main clinical features of MPA are listed in table 2.

Table 2 Microscopic polyangiitis: clinical features and organ or system involvement, expressed as percentages of the studied population (N = 235 in total)

Characteristics	Serra et al, 1984	Savage et al, 1985	D'Agati et al, 1986	Adu et al, 1987	Guillevin et al, 1999*
No. of patients	53	34	20	43	85
Mean age (years)	53	50	50	–	57
Sex ratio (male/female)	1.5	1.8	1	1.7	1.2
General signs (fever, asthenia, myalgias, arthralgias)	79	76	–	–	73
Hypertension	26	29	35	21	34
Kidney	100	100	100	100	79
Skin	60	–	35	53	62

Haemoptysis	23	32	–	–	–
Infiltrates	30	–	–	–	10
Pleural effusion	19	15	–	–	6
Gastrointestinal tract	51	–	–	56	30
Ear, nose, throat	30	–	–	20	–
Sinusitis	6	9	–	–	11
Eyes	30	–	–	28	–
Nervous system	28	–	–	–	–
Peripheral	19	18	15	14	58
Central	15	18	40	0	12
Heart	15	–	–	9	–

3.2.3.1 General symptoms and clinical presentation at disease onset

Most patients have some general systemic symptoms before MPA is diagnosed, such as myalgias, arthralgias and/or, more rarely, arthritis, that are present in 56–76% of patients at the time of diagnosis. An indolent course of several months, or even years, before diagnosis can be made, with mild general symptoms and/or even episodic, mild and ignored blood stained sputum.

3.2.3.2 Renal involvement

Rapidly progressive glomerulonephritis is a major feature of MPA (figure 18). Renal involvement appeared to be nearly universal in the first series of patients with MPA, but these cases were mainly reported by nephrologists (Primo et al, 2010). Initial renal manifestations are often silent, but detection of microscopic haematuria with or without proteinuria usually precedes renal function deterioration. Patients who have only renal involvement are often referred to as having kidney-limited disease or renal vasculitis. Most of these cases will evolve, if insufficiently treated, to MPA (or GPA).

Figure 18 Renal histology in a patient with microscopic polyangiitis showing vasculitis and glomerular scars.

3.2.3.3 Pulmonary involvement

The classic pulmonary manifestation of MPA is diffuse alveolar haemorrhage caused by pulmonary capillaritis. Moreover, like GPA or anti-glomerular basement membrane disease (Goodpasture), MPA can also be responsible for a pulmonary–renal syndrome. Haemoptysis or moderately bloody expectorations may precede severe pulmonary haemorrhage, which is characterised by dyspnoea and anaemia, and may progress to more diffuse alveolar damage and respiratory distress syndrome (Primo et al, 2010). Bronchial arteritis can also be found during histological examination of a lung biopsy specimen.

Interstitial lung fibrosis is a less well-recognised pulmonary manifestation of MPA, which may or may not follow alveolar haemorrhage. It has also been described as an isolated process confined to the lungs in some patients with anti-MPO pANCA, more frequently in the Japanese population. In a recent report from a Chinese cohort of patients with MPA, 19/67 presented with pulmonary fibrosis (Huang et al, 2014). These patients were older, mainly female and only six had an initially positive MPO-ANCA (the others became MPO-ANCA positive during follow-up).

3.2.3.4 Cutaneous manifestations

Skin lesions are found in half of patients with MPA. Maculopapular purpuric lesions of the lower limbs are the most frequent skin manifestations. Other lesions are vesicles, necrosis, ulcerations, nodules, splinter haemorrhages, livedo reticularis, hand and/or finger erythema, facial oedema and mouth ulcers. On histology, leukocytoclastic, but non-specific, vasculitis of the small vessels of the dermis, can be seen in the lesions.

3.2.3.5 Neurological involvement

Mononeuritis multiplex affects two-thirds of patients with peripheral nervous system involvement, followed by symmetric polyneuropathy. Necrotising vasculitis can be seen in 80% of sural nerve biopsies. CNS involvement and cranial neuropathies have been reported in around 10% of patients.

3.2.3.6 Gastrointestinal involvement

Abdominal pain is the most frequently reported gastrointestinal symptom, present in up to 50% of patients. Sometimes, bleeding or more severe small intestine or large bowel ischaemia, ulcerations and/or perforations may occur.

3.2.3.7 Other clinical manifestations

Cardiovascular complications in MPA are rare. Among 85 patients with MPA heart failure and/or pericarditis occurred at frequencies of 17.6% and 10%, respectively (Guillevin et al, 1999*). Severe acute congestive heart failure has been reported, but rarely with documented myocardial infarction. However, subclinical myocardial

infarctions may be more common. Ocular manifestations, such as eyelid inflammation, retinal cotton-wool spots, retinal vasculitis and/or choroiditis, may be seen in MPA, but rarely. Pertinently, mild, non-granulomatous, non-erosive, and thus non-specific, sinus inflammation may be noted in MPA. However, there is some controversy about even such non-specific ENT involvement, which is sometimes considered to be an excluding feature for the diagnosis of MPA when present and should prompt consideration of GPA as the alternative diagnosis, but this remains controversial.

3.2.4 Laboratory findings and complementary investigations

There is no specific laboratory test for diagnosing MPA. ANCA are detected in 60–80% of patients with MPA. The majority of ANCA detected are pANCA anti-MPO, although anti-PR3 can also rarely be found. Anti-MPO-ANCA are not as specific for MPA as anti-PR3-ANCA are for GPA, partly because they can also be found in EGPA, in about 5% of patients with GPA, in drug-induced AAV and in a variety of other different inflammatory disorders.

As in the other AAV, non-specific markers of inflammation are found in MPA: raised erythrocyte sedimentation rate, C-reactive protein level, platelet and white blood cell counts and low haemoglobin (normochromic normocytic anaemia) and serum albumin.

In patients with renal involvement, microscopic haematuria is present in almost all cases and may reflect disease activity, damage, infection or haemorrhagic cystitis/bladder malignancy due to cyclophosphamide therapy. The presence of red cell casts is highly suggestive of an active glomerulonephritis, but is difficult to detect in daily practice. Proteinuria can be found in >90% of patients, but is usually <3 g per 24 h.

Renal histology in patients with kidney manifestations is characterised by the presence of focal segmental thrombosing and necrotising glomerulonephritis. Extracapillary crescents are present in nearly all renal biopsies and often involve more than 60% of the glomeruli. The severity of renal impairment and the prognosis for renal function has been reported to correlate with the presence of glomerular sclerosis and tubular damage, and active glomerular disease with crescents (Berden et al, 2010).

Visceral angiography is not part of the usual diagnostic investigations of MPA. When performed, and based on the results of earlier series in which patients with MPA and PAN were mixed, it is usually normal in MPA, without stenoses and/or microaneurysms as found in PAN (however, rare cases of anti-MPO-ANCA-positive MPA with visceral microaneurysms have been reported).

3.2.5 Pathogenesis

Animal models (Heeringa et al, 1998; Xiao et al, 2002*) support a direct pathogenic role of anti-MPO pANCA. MPO constitutes about 5% of all neutrophil proteins and is present in the cytoplasmic primary granules at high

concentrations. The experimental model from Xiao et al is based on the passive transfer of anti-murine MPO antibodies or splenocytes, obtained from MPO-deficient mice immunised with murine MPO, into mice lacking T and B cells (with inactivated recombina-activating gene 2—rag2) and into wild-type mice. This resulted in the development of severe necrotising crescentic glomerulonephritis and systemic necrotising vasculitis, including haemorrhagic pulmonary capillaritis, closely resembling human disease. Little et al using an experimental rat model, showed that immunisation of a particular rat strain with human MPO led to the synthesis of antibodies recognising murine MPO and to the development of systemic vasculitis with pauci-immune glomerulonephritis (Little et al, 2006). Subsequently, passive transfer of purified IgG anti-MPO from immunised rats into non-immunised rats also induced systemic vasculitis.

Despite these animal models, evidence that MPO-ANCA alone can be pathogenic in humans remains inconclusive. A case of transplacental transfer of MPO-ANCA has been reported to result in neonatal MPA (Bansal and Tobin, 2004). However, a subsequent case report documents a successful pregnancy of a healthy newborn despite transplacental transfer of MPO-ANCA (Silva et al, 2009).

The potential role of T cells in MPA, as opposed to GPA, is poorly established. The mouse model of Xiao et al described above, showed that vasculitis is caused by anti-MPO alone and not by T cells.

Recent reports have shown that activation of the alternative pathway of complement is required for development of vasculitis. Complement is activated by factors released by neutrophils stimulated by ANCA, and C5a can prime neutrophils to enhance ANCA-induced neutrophil activation (Xiao et al, 2005; Cartin-Ceba et al, 2012). In an animal model, mice lacking the neutrophil receptor for C5a did not develop glomerulonephritis (Schreiber et al, 2009). Thus, the complement system is a potential target for treatment in human AAV (Kallenberg et al, 2013) currently being investigated (Jayne et al, 2017).

In addition, modifications in the Fc gamma receptor, present in neutrophils, have also been involved in the pathogenesis and modulation of the disease (Jennette and Falk, 2013b).

Epigenetic and genetic factors may have a marked influence on the pathogenesis and severity of the disease (Jennette et al, 2011b; Xiao et al, 2013). Recently, a genome-wide association study implicated a genetic influence of HLA-DQ in MPO-ANCA disease, suggesting that GPA and MPA are distinct genetic entities (Lyons et al, 2012).

The main putative pathogenic mechanisms of AAV are shown in figure 19. This schematic representation applies to MPA and probably also to GPA. For EGPA, the role of ANCA is less clear cut, and there is likely to be an important role for the eosinophil in some manifestations.

Figure 19 Schematic representation of the main hypothesised antineutrophil cytoplasmic autoantibody (ANCA)-associated vasculitis pathogenic mechanisms. IL, interleukin; MPO, myeloperoxidase; PR3, proteinase 3; TNF, tumour necrosis factor. The trigger(s) for neutrophil activation and the production of pathogenic ANCA remain putative. Dysregulated T cells and dendritic cells may play important and/or contributory roles. Once primed, neutrophils become further activated by the fixation of ANCA to MPO (or PR3) and Fc gamma receptors expressed on the cell surface. Surface expression may be constitutively upregulated in patients with granulomatosis with polyangiitis (Wegener's) (and further increased after neutrophil priming). Activated neutrophils are attracted to target vessels and tissues through the expression of several adhesion molecules and possibly other molecular tracking systems, such as toll-like receptors. The release, by activated neutrophils, of reactive oxidative species, proteinases (including PR3 or MPO) and cytokines, results in endothelial and tissue injury (vasculitis). Activated neutrophils also activate an alternative complement pathway and cause the release into the bloodstream and locally injured tissues of neutrophil extracellular traps (NETs) (potentially toxic locally, especially in the kidneys, and/or contributing to the perpetuation of autoimmunity in ANCA-associated vasculitis).

In MPA, there are a substantial number of ANCA-negative patients in whom all these models fail to explain the pathogenesis of their disease. In these cases, anti-LAMP-2 might have a pathogenic role. The presence of anti-endothelial cell antibodies and a predisposed innate immune system may also be associated with the vascular inflammation found in those patients (Damianovich et al, 1996).

3.3 Eosinophilic granulomatosis with polyangiitis (Churg–Strauss)

3.3.1 Classification

EGPA (Churg–Strauss) is a disorder characterised by pulmonary and systemic small vessel vasculitis, extravascular granulomas and hypereosinophilia, which characteristically occurs in people with background late-onset asthma and allergic rhinitis. It was first described in 1951 by two pathologists, Churg and Strauss, who established three major histological criteria: tissue infiltration by eosinophils, necrotising vasculitis and extravascular granulomas (Churg and Strauss, 1951). However, these three histological components rarely coexist temporally or spatially in the patients we see today. In 1984 Lanham et al proposed clinical criteria that are useful for the diagnosis of EGPA: the association of asthma, blood eosinophil count $>1500/\text{mm}^3$ and symptoms of systemic vasculitis affecting at least two extrapulmonary sites (sensitivity of 95% and specificity of 95%). In 1990, the ACR proposed six classification criteria for EGPA in patients with documented vasculitis, with four being necessary for diagnosis of EGPA with 85% sensitivity and 99.7% specificity (Masi et al, 1990).

3.3.2 Epidemiology

EGPA is the least common of the AAV. Its annual incidence is between 0 and 4 per million population and prevalence is between 7 and 22 per million population (Mohammad et al, 2009). The mean age at diagnosis of EGPA is around 45–50 years, with a male to female ratio of about 1.

3.3.3 Clinical features

The main clinical features of EGPA are described in table 3.

3.3.3.1 Natural history of EGPA

Lanham et al identified three phases of the disease. The prodromal period may last for over 30 years and consists of asthma and other common and non-specific allergic manifestations (allergic rhinitis and nasal polyposis). The second phase of the disease is characterised by the onset of peripheral blood and tissue eosinophilia with Löffler's syndrome, chronic eosinophilic pneumonia or eosinophilic gastroenteritis; the eosinophilic infiltrative disease may remit and recur over the years before systemic vasculitis appears and defines the third phase of the disease, although these three phases do not necessarily follow one another in this order. Systemic vasculitis emerges a mean of 4–9 years after the onset of asthma, with reports indicating a maximum latency of 30 years.

ENT, ear, nose and throat; GI, gastrointestinal.

3.3.3.2 General symptoms

General symptoms, such as fever or weight loss, are present in most patients and their development in patients with asthma should alert physicians to the possibility of EGPA onset.

3.3.3.3 Musculoskeletal symptoms

Arthralgias are frequent and often occur during the first days or weeks. Arthritis with local inflammatory findings is rare, and joint deformity and radiographic erosions do not occur. Although arthralgia can affect all joints, it predominates in larger joints. Myalgias are present in half of patients.

3.3.3.4 Pulmonary manifestations

Asthma is the central feature of EGPA and precedes the systemic manifestations in nearly all cases. Unlike common asthma, it appears relatively late, around the age of 35 years. The severity and frequency of the asthmatic attacks usually increase until the onset of vasculitis. Although dramatic remission of asthma may occur when vasculitis emerges, asthma usually becomes more severe during the weeks preceding vasculitis and often glucocorticoid-dependent, with some patients requiring admission to hospital owing to respiratory failure. Chest radiographs are often abnormal and 38–77% of patients have transient and labile pulmonary

infiltrates, which rarely cavitate, in contrast to GPA. Pulmonary infiltrates, when present during the second phase of the disease, and in association with asthma and hypereosinophilia, may mimic chronic eosinophilic pneumonia. According to recent prospective studies, pleural effusion is rarely present at the time of diagnosis and was seen in only 3% of patients, usually as an eosinophil exudate.

3.3.3.5 ENT involvement

Maxillary sinusitis is common and 70% of patients have a history of allergic rhinitis and/or sinus polyposis (figure 20).

Figure 20 *Left maxillary sinusitis with osteoformation in a patient with eosinophilic granulomatosis with polyangiitis (Churg–Strauss).*

3.3.3.6 Neurological involvement

Peripheral neuropathy, usually mononeuritis multiplex, is found in 45–75% of patients, and its occurrence is highly suggestive of the diagnosis in a patient with asthma. CNS involvement is relatively rare. It occurs in 5–10% of patients and includes strokes and pachymeningitis.

3.3.3.7 Cutaneous lesions

Purpura is seen in nearly half of cases and subcutaneous nodules in 30%. Skin biopsies may show extravascular and eosinophilic granulomas. These nodules are the most distinctive skin lesions of EGPA. Other cutaneous manifestations have been reported, including Raynaud’s phenomenon, livedo reticularis, urticarial lesions, patchy skin necrosis, infiltrated papules, vesicles or bullae and toe or finger ischaemia.

3.3.3.8 Cardiac involvement

Cardiac involvement is common in EGPA and one of the hallmarks of the disease, because it is the major cause of death. The reported incidence of cardiac manifestations depends on the method used for their assessment, varying from 17%, when using electrocardiography, to 92%, in post mortem studies.

The spectrum of cardiac features in patients with EGPA includes pericarditis, myocarditis, arrhythmias and, more rarely, angina pectoris, myocardial infarction and sudden death. Echocardiography may show several abnormalities, including diminished contractile parameters, which are not specific for vasculitis. Studies (Marmursztejn et al, 2009; Dennert et al, 2010) have shown that cardiac MRI has a higher sensitivity in detecting cardiac involvement of the disease and it has been proposed for the evaluation of patients, with or without clinical symptoms. However, its prognostic value remains uncertain. For patients with no other signs of cardiomyopathy, cardiac magnetic resonance imaging-detected anomalies do not seem to adversely affect prognosis or outcome (Dunogu   et al, 2015).

3.3.3.9 Gastrointestinal involvement

Digestive tract symptoms, including abdominal pain, diarrhoea and bleeding, occur in 30–60% of patients. Bowel perforation is the most severe GI complication and is one of the major causes of death. Vasculitis and granulomas may be present throughout the GI tract, but occur more often in the small intestine and/or colon (Pagnoux et al, 2005).

3.3.3.10 Other manifestations

Renal disease can be seen but is uncommon in EGPA, especially in comparison with GPA and MPA. Depending on the series, it is usually found in <25% of patients. The glomerular lesion that typifies EGPA is focal segmental glomerulonephritis with necrotising features including crescents, indistinguishable from the other AAV; however, kidney disease is considered less severe, rarely causing renal failure. Other lesions are also possible, such as vasculitis, eosinophilic interstitial infiltrates and granuloma.

The eye can also be involved, and uveitis, retinal vasculitis, episcleritis and/or conjunctival nodules have been described.

3.3.4 Patient subgroups according to ANCA status

EGPA is associated with ANCA, mainly anti-MPO pANCA; however, only 25–40% of patients with EGPA are ANCA-positive. In those patients there is an increased frequency of renal involvement, constitutional symptoms, purpura, alveolar haemorrhage, mononeuritis multiplex and/or CNS involvement.

In ANCA-negative patients vasculitis has been reported less frequently in histological specimens, and eosinophil tissue infiltration is often more prominent. Furthermore, there is a higher incidence of cardiomyopathy, pericarditis, livedo and/or pulmonary infiltrates in those patients (Sable-Fourtassou et al, 2005; Sinico et al, 2005).

After a mean follow-up of 3 years, patient survival and relapse rates did not differ according to patient ANCA status, but long-term follow-up studies suggested a higher relapse rate in ANCA-positive patients and a higher mortality rate in ANCA-negative patients because the latter more often had cardiomyopathy (Baldini et al, 2009; Comarmond et al, 2013).

3.3.5 Complementary investigations and differential diagnosis

Apart from ANCAs, other abnormal findings can be found in EGPA. Eosinophilia is present in active untreated disease and often $>1500/\text{mm}^3$ (97% of patients). The absence of eosinophilia may be explained by prior glucocorticoid administration for asthma. The mean eosinophil count at diagnosis is around $7500/\text{mm}^3$, but the eosinophil count can exceed $50\,000/\text{mm}^3$. The association of eosinophilia $>1500/\text{mm}^3$ with asthma is highly suggestive of a diagnosis of EGPA. Serum IgE is raised in more than 75% of patients.

The presence of isolated eosinophilia should raise the possibility of parasitic infection (especially with nematodes) and allergies (mainly drug allergies). The other main differential diagnosis to consider is hypereosinophilic syndrome, characterised by the presence of persistent peripheral blood eosinophilia $>1500/\text{mm}^3$ and eosinophil-mediated organ damage. Recent techniques have become available to identify certain subtypes of hypereosinophilic syndrome and therefore rule out EGPA. The myeloproliferative subtype is known to be associated with FIP1-like 1 platelet-derived growth factor receptor-alpha (FIP1L1-PDGFR α) and the lymphocytic subtype with T cell antigen receptor rearrangements. In some cases, the differential diagnosis can only be definitively established during follow-up, especially in ANCA-negative patients with no histologically proven vasculitis and negative molecular genetic testing (Ogbogu et al, 2009).

Alternative diagnoses should be considered, particularly in patients with unusual clinical features and/or in those who are resistant to glucocorticoids and/or do not have asthma.

3.3.6 Histology

The two characteristic lesions for the diagnosis of EGPA are vasculitis and extravascular necrotising granulomas, usually associated with eosinophilic infiltrates. Vasculitic lesions may be granulomatous or non-granulomatous, and typically involve small arteries. In the lungs, the histological features of EGPA include necrotising vasculitis and areas resembling eosinophilic pneumonia. Extrapulmonary lesions are more commonly found in the heart and gastrointestinal (GI) tract than in the kidney. The most common histological lesions seen in the heart are granulomatous and/or eosinophilic infiltration of the myocardium and coronary

vessel vasculitis. Vasculitis and granulomas can be present throughout the GI tract, but occur more often in the small intestine and/or colon (Pagnoux et al, 2005). Cutaneous and subcutaneous lesions, even the so-called Churg–Strauss granulomas, lack diagnostic specificity and 50% of such lesions occur in a variety of systemic diseases other than EGPA.

3.3.7 Aetiopathogenesis

The pathophysiology of EGPA can be divided into three aspects, corresponding to the three main phases of the natural history of EGPA: the pathogenic role of T helper type 2 (Th2) lymphocytes in asthma; eosinophils infiltrating tissues; and anti-MPO-ANCA, possibly playing an additional role in the occurrence of some vasculitis lesions in the third of patients who are ANCA-positive. In addition, as in the other forms of AAV, genetic factors influencing the aetiopathogenesis of the disease are likely to be important, such as the association with HLA-DRB4 (Vaglio et al, 2013).

Th2 cells orchestrate the recruitment and activation of the primary effector cells of the allergic response, the mast cells and the eosinophils, through the release of cytokines such as interleukin (IL)-4, IL-5 and IL-13. Activation of these cells results in the release of a plethora of inflammatory mediators that individually or in concert contribute to producing the symptoms of asthma. IL-4 is required for class switching from IgG to IgE, and IL-5, in association with IL-3 and granulocyte/macrophage-colony stimulating factor, is particularly important in regulating eosinophil proliferation. The hypothesis that some allergens or infections (parasitic or bacterial) might trigger CD4 Th2 cells and cause a massive expansion of eosinophils needs to be confirmed. Indeed, desensitisation and vaccinations have been implicated as potential triggering factors for the development of EGPA.

EGPA cases have also been sporadically reported in relation to the use of different drugs, such as macrolides, carbamazepine or quinine. The possible contribution of leukotriene receptor antagonists (LTRA; zafirlukast, montelukast and pranlukast) to the development of EGPA has been highlighted. However, LTRA treatment usually provides the opportunity for a substantial tapering or withdrawal of asthma treatment, especially glucocorticoids, which in turn may unmask an underlying and previously incomplete and unrecognised disease, a ‘forme fruste’ of EGPA. It remains to be determined whether the onset of EGPA following the initiation of omalizumab (anti-IgE monoclonal antibody) in asthmatic patients results from the same mechanism (Puéchal et al, 2008). EGPA has also been reported, but much less frequently, with the use of other systemic glucocorticoid-sparing treatments, such as the long-acting β 2-agonist salmeterol, disodium cromoglycate and inhaled fluticasone, and even just after the onset of tapering of inhaled or oral glucocorticoids, without the combination or the introduction of any other anti-asthma drug. Despite EGPA being considered a Th2-mediated disease, a Th17 increased response and a Th1 decreased frequency have been found in active stages

of the disease, suggesting that Th17 and Th1 may also play important roles in the pathogenesis of EGPA (Saito et al, 2009).

Patients with EGPA usually show marked peripheral blood eosinophilia with various degrees of activation and increased levels of circulating IgE and IgE-containing immune complexes. Eosinophils contain large amounts of highly cationic proteins, respectively named eosinophil cationic protein, major basic protein, eosinophil-derived neurotoxin and eosinophil peroxidase (Roufosse, 2013). These cationic proteins, released after eosinophil activation, have been shown to be cytotoxic and may be directly responsible for some of the classic disease features of EGPA. In addition, eosinophils are major sources of IL-25, a cytokine driving Th2 lymphocytes differentiation (Terrier et al, 2010).

As previously mentioned, ANCA are found in about 25–40% of patients with EGPA, directed towards MPO in most cases. Even though the pathogenic role of anti-MPO-ANCA in systemic vasculitis has been recently shown, their role has not been demonstrated in EGPA and none of the anti-MPO animal models developed features of EGPA, such as eosinophil tissue infiltration. Thus, the respective role of eosinophils, lymphocytes and ANCA may differ in patients with EGPA, based on their ANCA status and the phase of their disease. Other as yet unknown mechanisms may also be involved in EGPA.

3.4 Treatment of ANCA-associated vasculitides

Before the advent of immunosuppressive treatment, AAV carried a 2-year mortality rate of 93%. The introduction of glucocorticoids in the 1950s and cyclophosphamide-based regimens in the 1970s (Fauci et al, 1978), has transformed the survival rates, now approaching 80% at 5 years (Flossmann et al, 2011*) and 75–85% at 10 years (Puechal et al, 2016).

Treatment should be based on several factors after careful analysis of classification, expected outcome, aetiology, pathogenesis, severity, comorbidity and age; however, inducing and maintaining disease remission, using the least cytotoxic drugs, should be the main goal.

To help the clinician choose the most effective treatment and to avoid overtreatment, the French Vasculitis Study Group established the Five-Factor Score (FFS), which has significant prognostic value in PAN, MPA and EGPA (not validated for GPA). The presence of any of the following five factors indicates higher mortality: proteinuria >1 g/day, renal insufficiency (creatininaemia >140 µmol/L), cardiomyopathy, GI manifestations and CNS involvement (Guillevin et al, 1996; Gayraud et al, 2001). When the FFS was 0, mortality at 5 years was 12%, but rose to 46% when the FFS was ≥2. A revised FFS was recently published and includes age >65 years as another measure of poor prognosis and the presence of ENT manifestations as a parameter of good prognosis in GPA and EGPA (table 4). However, this latter revised FFS has not yet been validated on non-French patients, and thus should not be applied when deciding optimal treatment (Guillevin et al, 2011*). The Birmingham

Vasculitis Activity Score (BVAS), a validated tool for small- and medium-vessel vasculitis, can be used to determine the intensity of treatment, with higher scores being associated with higher mortality (Flossmann et al, 2011*). It was validated for assessment of disease activity in systemic vasculitis in 1994 (Luqmani et al, 1994), modified in 1997 for use in collaborative European trials (BVAS v.2) (Luqmani et al, 1997*), in 2001 to produce a disease-specific instrument for GPA (BVAS/Wegener's granulomatosis) (Stone et al, 2001) and again in 2009 with the removal of redundant and/or uncommon items (BVAS v.3) (Mukhtyar et al, 2009b*). The last version consists of a list of 56 items considered to be vasculitis manifestations with a numerical weight attached to each item, and each organ system has a ceiling score (figure 21). These scores reflect the proportional importance of each manifestation and each organ system and are designed to document new or worsening clinically active vasculitis that would be likely to require immunosuppressive therapy or an increased clinical monitoring regimen. In the recent EULAR/ERA-EDTA recommendations and British Society for Rheumatology guidelines for the management of AAV, BVAS is used to define patients' disease states (Yates et al, 2016; Ntatsaki et al, 2014). BVAS is an effective tool in routine care for the management of most patients with active vasculitis. It provides a valuable checklist to help clinicians remember the most common manifestations of vasculitis when assessing patients with suspected or diagnosed disease. It has the advantage of being able to quantify disease activity, and provide qualitative data for each organ system involved. However, one of the limitations of BVAS is the failure to capture grumbling disease lasting for >3 months when there has been no increase in disease activity. (More information on BVAS is given in the EULAR online course on rheumatic diseases—module 24.)

Table 4 Original and revised Five-Factor Score (FFS)

Original FFS items (1996)	Revised FFS items (2009)	Mortality rate at 5 years	
Creatinine >140 µmol/l	Creatinine >150 µmol/l	FFS = 0	12%
		Revised FFS = 0	9%
Proteinuria >1 g/24 h	Age >65 years		
Specific cardiomyopathy	Specific cardiomyopathy	FFS = 1	26%
		Revised FFS = 1	21%
Specific gastrointestinal involvement	Specific gastrointestinal involvement		
Specific central nervous system involvement	Absence of ear, nose and/or throat manifestations (GPA and EGPA only)	FFS = 2	46%
		Revised FFS ≥2	40%

These scores are to be calculated at the time of diagnosis only (not validated at the time of relapse or during follow-up). The original FFS can be applied to patients with polyarteritis nodosa (PAN), microscopic polyangiitis (MPA) and eosinophilic granulomatosis with polyangiitis (Churg–Strauss) (EGPA). It is not validated for granulomatosis with polyangiitis (Wegener's) (GPA). A revised version of the FFS was designed in order to be used also for GPA patients. It is based on the analysis of a large French cohort of patients with PAN, MPA, EGPA and GPA. The ear, nose and throat (ENT) item (absence of ENT manifestations) only applies to patients with GPA and EGPA (for MPA and PAN, only the other four parameters are to be used for the calculation of the score).

Treatment recommendations have been devised by the European League Against Rheumatism (EULAR) and British Society for Rheumatology to help physicians in the management of patients with AAV (Hellmich et al, 2007; Mukhtyar et al, 2009a*; Ntatsaki et al, 2014; Yates et al, 2016).

All current major trials on ANCA-associated vasculitides are listed and detailed on the European Vasculitis Study Group (EUVAS), French Vasculitis Study Group and/or Vasculitis Clinical Research Consortium websites at: <http://www.vasculitis.org>; <http://www.vascularites.org>; and <http://rarediseasesnetwork.epi.usf.edu/vcrc/index.htm>, respectively.

An algorithm for AAV treatment according to disease severity is proposed in figure 22 and a summary of the induction and maintenance treatments is listed in table 5.

Figure 22 Treatment algorithm for ANCA-associated vasculitides. In grey: potential alternative agents or drugs under investigation. AAV, ANCA-associated vasculitis; ADA, adalimumab; ANCA, antineutrophil cytoplasmic antibody; ATG, antithymocyte globulin; AZA, azathioprine; BVAS, Birmingham Vasculitis Activity Score; CYC, cyclophosphamide; DSG, deoxyspergualin; EGPA, eosinophilic granulomatosis with polyangiitis; FFS, Five-Factor Score; GC, glucocorticoid; GPA, granulomatosis with polyangiitis; IFX, infliximab; IVIg, intravenous immunoglobulin; LEF, leflunomide; MMF, mycophenolate mofetil; MPA, microscopic polyangiitis; MTX, methotrexate; PEX, plasma exchange; RTX, rituximab.

Please see in-depth discussion II of the EULAR online course on rheumatic diseases, Module 24, for more details on the current and future use of biologics in AAV.

*GPA and MPA; **GPA; ***EGPA.

¹In the NORAM trial (de Groot et al, 2005*) methotrexate was not inferior to cyclophosphamide for newly diagnosed patients with early systemic GPA or MPA without organ-threatening or life-threatening disease and a creatinine <150 µmol/L.

²Increased risk of carcinoma (in combination with cyclophosphamide).

³In the CHUSPAN2 trial (Puéchal et al, 2017), azathioprine adjunction to glucocorticoids for remission-induction of nonsevere systemic necrotizing vasculitis did not improve remission rates, lower relapse risk, spare steroids or diminish the EGPA asthma/rhinosinus-exacerbation rate.

3.4.1 Induction therapy

3.4.1.1 Regimen for MPA and EGPA with poor prognostic factors and systemic/severe forms of GPA

Patients with MPA or EGPA with poor prognostic factors (FFS ≥ 1) and patients with systemic/severe forms of GPA should all receive an induction regimen based on the combination of glucocorticoids and an immunosuppressant agent, with cyclophosphamide (CYC) or rituximab (RTX) as first choice.

Methylprednisolone pulses (usually 7.5–15 mg/kg intravenously over 60 min repeated at 24 h intervals for 1–3 days) are still used at the start of treatment for some patients with severe forms of vasculitis because of their rapid action and relative short-term safety, although the evidence for their use is poor and there is growing concern about their cumulative effects. Oral glucocorticoids are given at a dose of 1 mg/kg/day of prednisone-equivalent, usually as a single morning dose. After 3 weeks of the full dose, the glucocorticoid dose should be progressively tapered and, in the absence of relapse, glucocorticoids can be stopped after 9–18 months. However, the optimal duration of glucocorticoid therapy is debated, and there is concern about the toxicity of glucocorticoids, especially with regard to the risk of infection (Walsh et al, 2010).

CYC, an alkylating immunosuppressant agent, can be given orally and continuously or using an intravenous bolus. Comparison of the two CYC regimens (i.e., oral vs intravenous) shows them to be equally effective at controlling disease activity without differences in survival, but pulse CYC therapy is associated with a lower cumulative dose and toxicity (Guillevin et al, 1997; de Groot et al, 2009*). However, pulse CYC may expose the patient to a higher subsequent risk of relapse (Harper et al, 2012). The CYC dose, as well as the total number and frequency of pulses when administered intravenously, should be adjusted according to the patient's condition, especially age, renal function and haematological data. Initial pulse doses used range from 0.5 g to 1.2 g at intervals of 2 weeks initially for one month, then every 3 weeks until achievement of remission. In the EUVAS trials, the CYC pulse dose is of 15 mg/kg (max 1.2 g) every 2 weeks for the first 3 pulses, followed by infusions every 3 weeks for the next 3–6 pulses. The oral CYC dose is 2 mg/kg/day, usually with a maximum of 200 mg/day. Sufficient hydration is mandatory to limit the risk of bladder toxicity of CYC metabolites (especially acrolein). The use of sodium 2-mercaptoethane sulfonate (mesna) and a total of 2–3 litres of fluid

are recommended during pulse therapy. Oral CYC should be taken in the morning with a large glass of water and the patient should remain well hydrated over the next 24 h.

CYC has been the usual induction agent for decades and most physicians treating vasculitis are familiar with its use, including the management and prevention of its potential late-onset adverse events, which are closely related to the given cumulative dose. However, RTX, a genetically engineered chimeric murine/human IgG1k monoclonal antibody directed against the CD20 antigen expressed on the surface of B lymphocytes, is now considered an equally effective alternative treatment.. The RAVE and RITUXVAS trials have shown that RTX is not inferior to CYC for inducing remission in generalised ANCA-positive GPA, MPA and renal limited vasculitis (Jones et al, 2010*; Stone et al, 2010*). RTX was given in these two studies in combination with glucocorticoids and at a dose of 375 mg/m² every week for a total of four injections. However, an alternative might be 1 g every 2 weeks, for a total of two injections (Guerry et al, 2011). Notably, the frequency of infections, mainly bronchitis and pneumonia, was no worse than with CYC-based induction, possibly related to the concomitant use of high doses of glucocorticoids. There have been rare cases of progressive multifocal leukoencephalopathy due to the JC virus in patients with vasculitides, both with and without RTX treatment, suggesting that RTX may be selectively associated with JC virus infection (Molloy and Callabrese, 2009; Molloy and Callabrese, 2012). In addition, there is controversy about patients with GPA with granulomatous manifestations, in whom therapeutic responses may be slower and less dramatic (Aries et al, 2006; Aouba et al, 2008). There are no controlled prospective studies using RTX in patients with ANCA-negative disease, but successful RTX treatment in ANCA-negative GPA has been reported (Khan et al, 2010), highlighting the possible pathogenic role of other antibodies (Chen et al, 2009). Some case reports and small series also suggested that RTX might have some efficacy in refractory EGPA (ANCA-positive and -negative) (Cartin-Ceba et al, 2011; Thiel et al, 2013); prospective randomised trials are ongoing (REOVAS, ClinicalTrials.gov Identifier: NCT02807103).

There is no strong evidence for mycophenolate mofetil (MMF) as an induction agent in AAV. Two small studies involving a total of 76 Chinese patients with mostly mild to moderate kidney involvement but not severe lung haemorrhage or central nervous system involvement (>98% MPA) suggested that it might be a useful alternative in patients with generalised disease (Hu et al, 2008; Han et al, 2011). A randomised controlled trial involving 140 patients with new-onset of early systemic and generalised GPA/MPA compared MMF to intravenous CYC as an induction agent (MYCYC, ClinicalTrials.gov identifier: NCT00414128). Preliminary 6-month results were unable to show non-inferiority of MMF and a standard glucocorticoid taper, in comparison to CYC. However, MMF and a non-fixed dose of glucocorticoids demonstrated non-inferiority. In addition, the relapse rates after 6-months were higher in patients who had received MMF, but confined to the PR3-ANCA subgroup. Therefore, these studies suggest that MMF induction may be considered in patients with MPA / MPO-ANCA associated vasculitis without severe renal manifestations (Jones and Walsh, 2012; Jayne and Rasmussen 2015).

3.4.1.2 Regimen for MPA or EGPA without poor prognostic factors and for localised/early-systemic forms of GPA

It was shown that patients with MPA or EGPA without factors for poor prognosis (FFS = 0) at the time of diagnosis can be successfully treated with prednisone alone, with immunosuppressant agent(s) given only as a second-line treatment if disease activity persists or a relapse occurs despite glucocorticoid therapy.

Traditionally, glucocorticoids are started orally at a dose of 1 mg/kg/day of prednisone or equivalent. As described above, after 3 weeks of the full dose, the glucocorticoid dose should be gradually tapered. The relapse or failure rate seen in patients with MPA or EGPA treated with prednisone alone is high, but the 7-year survival rate is 79%. The addition at diagnosis of an immunosuppressant agent may lower the relapse rate of these patients with FFS = 0, but the balance between benefits and toxicity is narrowed and study results do not favour the systematic first-line use of CYC in combination with glucocorticoids (Ribi et al, 2008; Ribi et al, 2010). Azathioprine (AZA) - a less toxic drug - has been investigated in a study recruiting patients with EGPA, MPA and PAN (Puéchal et al, 2017). However, it failed to demonstrate a decrease in treatment failure or relapse, did not show a steroid-sparing effect and did not lower EGPA patients' rate of asthma/sinonasal disease exacerbations. Alternative therapies, such as MTX, need evaluation.

In contrast to MPA and EGPA, the combination of glucocorticoids and an immunosuppressant agent is required in all patients with GPA. Patients with a localised/early-systemic form of GPA can be treated initially with glucocorticoids and methotrexate (MTX), achieving similar responses to CYC. Although, MTX was shown to be inferior to CYC in preventing a relapse in the EUVAS NORAM trial (de Groot et al, 2005*), this was possibly explained by the trial protocol, which required withdrawal of MTX after 12 months. Thus, when effective, it should be continued for several years. Non-randomised studies suggested that co-trimoxazole (trimethoprim-sulfamethoxazole) could be used for remission induction in GPA for upper airway disease or localised disease. However, in a study evaluating 26 patients with localised GPA, initial treatment with trimethoprim-sulfamethoxazole was not sufficient in three-fourths of them due to failure or progression to early systemic or generalised disease (Holle et al, 2010).

3.4.2 Maintenance treatment

Once remission is achieved with CYC, patients can be switched to a less toxic immunosuppressant agent for maintenance, often AZA or MTX, neither one being clearly better than the other (Pagnoux et al, 2008b*), or RTX which has been shown to be superior to AZA at maintaining remission of GPA and severe MPA in a randomized controlled trial (Guillevin et al, 2014*).

The AZA dose is 2 mg/kg/day and the MTX dose is 0.3 mg/kg, delivered once weekly, up to 25 mg/week, orally or subcutaneously. It remains uncertain whether changing to AZA after 3–6 months of induction with CYC is as

effective as changing after 12 months (Walsh et al, 2014), but patients are usually switched to maintenance treatment after six to nine intravenous pulses or 3–4 months of oral CYC (Jayne et al, 2003*). The recently published REMAIN trial has compared different lengths of maintenance therapy with AZA (2 vs 4 years of maintenance) in GPA, MPA and renal-limited vasculitis patients achieving complete remission after induction with CYC and corticosteroids (Karras A et al, 2017). A longer course of AZA and prednisone has been found to be associated with a lower relapse rate (62.7% vs 22.0%), especially in those patients with ANCA persistently positive after induction therapy.

RTX for maintenance of remission in AAV has been investigated in a prospective randomised controlled study (MAINRITSAN) comparing RTX with AZA (Guillevin et al, 2014*). The primary end point was the rate of major relapses at 28 months. One hundred and fifteen patients were included after remission achievement with CYC infusions. The RTX group received pre-emptive fixed low-dose maintenance re-treatment every 6 months (500 mg RTX, five infusions over 18 months) and was compared with the group receiving maintenance treatment with AZA (2 mg/kg/day for 12 months, 1.5 mg/kg/day for 6 months, then 1.0 mg/kg/day for last 4 months). In the RTX arm, 7/55 (12.7%) patients compared with 26/54 (48.1%) patients in the AZA arm had at least one major relapse. In the long-term analyses of MAINRITSAN-trial patients, RTX remained superior to AZA at maintaining remission of ANCA-associated vasculitides over 60 months, with no safety differences with AZA (Terrier et al, 2016). The cumulative glucocorticoid use was comparable between the 2 arms. RTX maintenance was associated with better overall survival, and ANCA-specificity and month-12 persistence were associated with higher subsequent relapse risk.

The best treatment schedule (RTX injection on demand or driven by surrogate markers such as CD19 level and/or ANCA titer), and its duration are being investigated in 2 randomized controlled trials. MAINRITSAN 2 (Clinicaltrials.gov identifier: NCT01731561) has compared two RTX regimens: 500 mg infusions according to ANCA status/titer and/or circulating CD19 B-cell reappearance versus systematic 500 mg infusions at fixed intervals of 6 months (controls) (Charles et al, 2016). AAV relapse rates for patients given individually tailored or systematic RTX-infusion schedules did not differ significantly. However, the experimental arm patients received fewer infusions and lower total RTX doses. The objective of the ongoing MAINRITSAN 3 trial (ClinicalTrials.gov identifier: NCT02433522) is to determine the optimal duration of the RTX maintenance treatment to prevent relapses (2 years or 4 years). In addition, RITAZAREM (ClinicalTrials.gov identifier: NCT01697267) is comparing a different RTX regimen (1 g every 4 months until month 20) with AZA for maintenance treatment (2 mg/kg daily for 24 months) in relapsing AAV patients after achievement of remission with RTX.

In addition, prospective randomised trials are ongoing to assess the role of RTX as maintenance therapy in EGPA patients (MAINRITSEG, ClinicalTrials.gov Identifier: NCT03164473).

Leflunomide (LEF) is another alternative to MTX or AZA. One study, involving 54 patients with GPA, compared LEF 30 mg/day with MTX up to 20 mg/week and showed significantly higher rates of relapse in the MTX group. However, this was balanced by an increased frequency of adverse events in the LEF group (Metzler et al, 2007). A recent systematic review and network meta-analysis of all randomised trials comparing non-biological remission maintenance treatments in adult patients with GPA or MPA showed comparable efficacy of MTX, AZA or LEF, and even suggested, albeit indirectly, that LEF might be best (Hazlewood et al, 2014). Further prospective randomised trials with LEF are needed for confirmation.

MMF 2 g/day was compared with AZA 2 mg/kg/day for the maintenance of remission in 156 patients with AAV after CYC induction in the IMPROVE trial. Relapses were more common in the MMF group and adverse event rates were similar between the groups. Therefore MMF should be considered only in patients who cannot tolerate the usual maintenance drugs (Hiemstra et al, 2010*).

Trimethoprim-sulfamethoxazole 960 mg twice daily has also been proposed as a maintenance agent in GPA and a small randomized study has shown that treatment with co-trimoxazole in monotherapy may reduce the incidence of relapses in GPA patients in remission (Stegeman et al, 1996); however, it may not be effective in maintaining remission, particularly in generalized GPA (Reinhold-Keller et al, 1996).

Other maintenance strategies, based on B cell depletion, are currently being evaluated. Belimumab, a human monoclonal antibody that inhibits B lymphocyte stimulator (BLyS), is being tested as maintenance treatment in MPA and GPA (BREVAS, ClinicalTrials.gov identifier: NCT01663623). The optimal duration of glucocorticoid treatment, and its effect on disease flares and/or relapses, is also being currently evaluated for GPA in the prospective TAPIR trial, where 60 patients in remission are randomized to either reduce their prednisone dose to 5 mg or 0 mg a day.

3.4.3 Adjunctive treatments

Prevention of opportunistic infections, such as *Pneumocystis jiroveci* pneumonia, with trimethoprim-sulfamethoxazole 960 mg three times a week, is mandatory in patients receiving CYC, throughout the CYC therapy and for 2–4 months after its discontinuation, and should also be considered in those receiving glucocorticoids and RTX.

All patients receiving treatment with glucocorticoids should follow local guidelines for the prevention of glucocorticoid-induced osteoporosis (Mukhtyar et al, 2009a*). Gastro-protection with proton pump inhibitors is also advisable.

Supportive care is also a very important part of the treatment of patients with vasculitis. Pain control, prevention of pressure sores and physical therapy are needed in the case of mononeuritis multiplex.

Introduction of angiotensin-converting enzyme inhibitors or angiotensin II receptor antagonists has been beneficial in patients with severe hypertension due to renal vasculitis.

3.4.4 Other treatments

Interest in the use of intravenous immunoglobulins (IVIg) to treat systemic vasculitis was stimulated by their successful prevention of coronary artery aneurysms in Kawasaki disease. The obvious advantage of IVIg is that they generate few severe side effects, which is unfortunately counterbalanced by their high costs and only short-term benefits. IVIg have been used in GPA, MPA and EGPA, especially in patients refractory to several immunosuppressant agents and high-dose glucocorticoids and/or those with a concomitant and severe infection or pregnant (Jayne et al, 2000; Martinez et al, 2008).

Plasma exchange can improve the outcome of patients with AAV and severe renal failure (serum creatinine $>500 \mu\text{mol/L}$ or 5.65 mg/dL). It has been shown to increase the rate of renal recovery and enable dialysis to be stopped at 1 year; however, it has no effect on longer-term renal function or survival and is not commonly undertaken in patients with plasma creatinine $<500 \mu\text{mol/L}$ (Jayne et al, 2007; Casian and Jayne, 2011). Plasma exchange (seven sessions over 14 days) is often used in patients with alveolar haemorrhage, based on the usual treatment for Goodpasture syndrome, but its benefit is still uncertain. A recent meta-analysis concluded that more data are needed to establish the long-term benefit of this treatment (Walsh et al, 2011). The aim of a current international prospective controlled trial (PEXIVAS, ClinicalTrials.gov identifier: NCT00987389) is precisely to better evaluate the place of plasma exchange in patients with AAV with less impaired renal function and/or alveolar haemorrhage.

CCX168 - an oral inhibitor of the complement C5a receptor has been evaluated in a limited number of AAV patients. The CLEAR study was designed to assess if different regimens of glucocorticoids, added to a standard induction with CYC or RTX, could be replaced by CCX168 without compromising efficacy in patients with mild-to-moderate renal involvement (Jayne et al, 2017). 86% of patients receiving CCX168 + low dose glucocorticoids and 81% of patients receiving CCX168 + no glucocorticoids had a non-inferior $\geq 50\%$ BVAS reduction at 12 weeks versus 70% of patients in the standard care group of high dose glucocorticoids. In another phase II study evaluating two different dose regimens of CCX168 plus standard high-dose glucocorticoids and either RTX or CYC, 30 mg CCX168 twice daily confirms to be an appropriate for further study in patients with AAV (Merkel et al, 2016).

Other agents have been tested and/or are under investigation in refractory GPA or MPA. The antithymocyte globulin has been used in patients with refractory GPA in the SOLUTION trial, achieving a 75% remission rate, but with a high number of adverse events (Schmitt et al, 2004). The humanized anti-CD52 monoclonal antibody, alemtuzumab (CAMPATH-1H), has led to sustained treatment free remissions in a group of 71 patients with relapsing and refractory GPA and MPA, but it is strongly immunosuppressive and has been found

to be associated with severe adverse events (Walsh et al, 2008). In addition, the SPARROW trial (ClinicalTrials.gov identifier: NCT01446211) is currently evaluating the efficacy of guselimumab (15-deoxyspergualin) in relapsing and refractory GPA and the ABROGATE trial (ClinicalTrials.gov identifier: NCT02108860) is evaluating the use of abatacept (CTLA4-Ig) for the treatment of relapsing, non-severe, GPA.

Inflammatory cytokines are important components in the disease development of AAV (Furuta and Jayne, 2014). TNF- α is associated with disease activity in AAV and its inhibition has already been tested. Complete or partial remission was obtained with infliximab in patients with refractory GPA in the early 2000s. However, after infliximab was stopped, relapses often occurred (Josselin et al, 2008). Etanercept, another TNF-blocking agent, has also been tested in AAV in conjunction with conventional treatment, including CYC, with the aim of reducing the relapse rate. It had no advantage for the prevention of relapse and, more importantly, six cancers were diagnosed during the trial, all in the etanercept arm (WGET, 2005). Eight additional solid malignancies developed in the patients receiving etanercept and five in the control group after the end of the trial (Silva et al, 2011). Adalimumab has also been proposed as an adjunctive and glucocorticoid-sparing agent for the treatment of severe AAV, but further studies are required (Laurino et al, 2010). TNF inhibitors are not currently recommended in the treatment of AAV.

Other inflammatory cytokines have shown to be increased in AAV, making them potential therapeutic targets. IL-6 serum levels were found significantly increased in patients with AAV, and treatment with tocilizumab was able to induce sustained disease remission in a patient with severe multisystem MPA, requiring further evaluation of this treatment option (Berti et al, 2015). Moreover, serum IL-17A and IL-23 levels were found highly elevated in acute AAV patients (Nogueira et al, 2010), supporting the importance for testing their inhibition with ustekinumab (anti-IL-12/23) and secukinumab (anti-IL-17A) in a formal trial setting.

In EGPA, the role of mepolizumab, a monoclonal anti-IL-5 agent, has been tested in two small pilot studies with a total of 17 patients (Kim et al, 2010; Moosing et al, 2011). In both studies a decrease in disease activity and a glucocorticoid-sparing effect was seen. However, this benefit was not sustained after switching to maintenance treatment with MTX (Herrmann et al, 2012). A double-blind, randomised, placebo-controlled study has investigated the efficacy and safety of a 300 mg dose of mepolizumab (administered subcutaneously every 4 weeks) compared with placebo over a 52-week study treatment period in patients with relapsing or refractory EGPA receiving standard of care treatment (Wechsler et al, 2017*). Mepolizumab led to significantly more accrued weeks of remission than placebo (28% vs. 3%), a higher percentage of participants in remission at both week 36 and week 48 (32% vs. 3%), and allowed to receive a daily dose of prednisolone or prednisone of 4 mg or less per day in a significantly higher number of patients (44% vs 7%). The benefit of the anti-IL-5 agent was mostly due to a better control of asthma and ENT manifestations in those patients and more uncertain of the vasculitis relapse rate. Therefore, it remains to be determined whether mepolizumab efficacy against EGPA mainly acts on asthma symptoms or also controls extrapulmonary vasculitis manifestations (Guillemin 2017).

Figure 23 Vasculitis Damage Index (VDI). BP, blood pressure; GFR, glomerular filtration rate.

VASCULITIS DAMAGE INDEX (VDI)		
<p>This is for recording organ damage that has occurred in patients since the onset of vasculitis. Patients often have co-morbidity before they develop vasculitis, which must not be scored. Record features of active disease using the Birmingham Vasculitis Activity Score (BVAS). A new patient should usually have a VDI score of zero, unless: (a) they have had vasculitis for more than three months of onset of disease and (b) the damage has developed or become worse since the onset of vasculitis</p>

Total VDI Score. Record the number of positive items (1 point for each). The VDI score can either increase or remain the same over time.		<input type="text"/>
Remember to carry forward any previous items of damage.		

3.5 Outcomes

In addition to the usual outcome measures (i.e., relapse and mortality rates), damage and quality of life should also be taken into account. Damage includes disease-related sequelae such as peripheral neuropathy or renal insufficiency, late drug-related adverse events, like CYC-induced bladder cancer and infertility, and other

problems such as premature atherosclerosis, where the underlying mechanism is less clear and/or multifactorial (Bourgarit et al, 2005; Pagnoux and Guillevin, 2005a). Damage can be evaluated using the Vasculitis Damage Index (VDI), which is a comprehensive and validated clinical checklist that records the accumulation of damage since the vasculitis onset (figure 23) (Exley et al, 1997). The damage items are often the direct result of previous disease activity, its treatment or other comorbidities. This is quite separate from BVAS and gives no indication of current disease activity. The VDI has been recommended by EULAR as an outcome parameter in clinical trials (Hellmich et al, 2007). Recently, Robson et al (2013) described up to 12 months of VDI data from 735 patients with AAV and up to 7 years of VDI data from 535 patients with AAV, all from the EUVAS trials. The long-term data showed that around one-third of patients had five or more items of damage, highlighting the importance of including damage as an outcome measure and raising awareness of potential comorbidities and treatment side effects when managing a patient with AAV. (in-depth discussion I of the EULAR online course on rheumatic diseases—module 24.)

3.5.1 GPA and MPA

A few patients die early during the first months of the disease from multivisceral involvement because treatment cannot control the disease (Pagnoux et al, 2008a; Flossmann et al, 2011*). Septicaemia can also develop during the first months of treatment owing to the intense initial treatment and indeed seems to be the major cause of early mortality in AAV. Viral infections usually arise later and result from the profound immunosuppression induced by the drugs prescribed to control the vasculitis. Rare cases of *Pneumocystis jiroveci* pneumonia have been described, mostly in lymphopenic patients ($<200/\text{mm}^3$).

Long-term causes of mortality and morbidity include cardiovascular disease, estimated at 14% within 5 years of diagnosis, as the possible consequence of vessel inflammation and long-term treatment with glucocorticoids; and malignancies, with an incidence ratio of 1.6–2.0 compared with the general population (higher risk in GPA than in MPA), as the possible consequence of long-term immunosuppressive therapy and, more hypothetically, underlying predisposition (Gaffo, 2013; Mahr et al, 2013).

Among all vasculitides, the relapse rate is probably highest in GPA, affecting up to 50–60% of patients at 5 years. All forms of GPA may relapse at any time, sometimes after several years or even decades of remission. Relapses also occur in MPA, reaching around 35% at 5 years, which is more than in PAN but less than in GPA. Relapse does not necessarily involve the same features as those at the original presentation and other organs can be involved; however, relapses are usually less severe than initial manifestations, mainly because the diagnosis tends to be made earlier.

The presence of PR3-ANCA (as compared with MPO-ANCA) carries a 1.62-fold greater risk of relapse (Walsh et al, 2012*). However, change of ANCA titre over time is not a useful predictor of relapse, and should not be used without clinical evidence of active disease to guide treatment (Finkelstein et al, 2007; Tomasson et al,

2012). A rapid reduction of glucocorticoid therapy of >0.8 mg a month was associated with a greater risk of relapse in a Japanese study of patients with MPA (Wada et al, 2012), but this was not reproduced in a Caucasian population (McGregor et al, 2012).

Relapses occur more frequently after maintenance treatment is stopped (two-thirds of relapses), but can also occur during treatment (Pagnoux et al, 2008b*; Hiemstra et al, 2010*). Conversely, excessively prolonged remission treatment can be harmful and not all patients relapse. Hence, the optimal maintenance regimen, its duration and the parameters on which it can be individually adjusted remain to be determined.

Patients with GPA presenting with ENT involvement and/or granulomatous manifestations (orbital pseudo-tumour, lung nodules) seem to relapse more often than those with renal vasculitis.

3.5.2 EGPA

The prognosis of EGPA has improved dramatically since the introduction of glucocorticoids and, when indicated, cytotoxic drugs. With adequate treatment, remission is rapidly obtained in $>80\%$ of patients. During follow-up, relapses occurred in 25–35%—half during the first year and later in the others—after a mean follow-up of 5 years. The 10-year survival rate is around 75–80%. Cardiac involvement is, and remains, the primary cause of death in patients with EGPA.

The EGPA Task Force recommendations defined relapse as the new appearance, recurrence or worsening of clinical EGPA manifestation(s), excluding asthma and/or ENT symptoms, requiring the addition, change or dose increase of glucocorticoids and/or other immunosuppressants (Groh et al, 2015*).

Indeed, asthma usually persists after recovery from vasculitis and $>75\%$ of the EGPA survivors in long-term remission have persistent asthma requiring maintenance treatment with low doses of prednisone (<10 mg/day) and/or inhaled glucocorticoids (Cohen et al, 2007; de Groot et al, 2009*). The availability of mepolizumab could represent a great opportunity to lower the need of corticosteroids in EGPA patients with refractory asthma.

4 Polyarteritis nodosa

4.1 Introduction

PAN was first described by Küssmaul and Maier in 1866 (Kussmaul and Maier, 1866). This necrotising systemic vasculitis predominantly involves medium arteries and can affect most organs in the body. The causes of primary and secondary PAN can be distinguished, since PAN can be the consequence of HBV infection (Trepo and Thivolet, 1970; Prince and Trepo, 1971) and sometimes other aetiological agents, like human immunodeficiency virus or, more controversially, hepatitis C virus (Saadoun et al, 2010). Among the vasculitides, PAN is now less common than in the past for reasons that will be discussed later.

4.2 Classification criteria

In 1990, the ACR established criteria for PAN classification, with 82.2% sensitivity and 86.6% specificity (Lightfoot et al, 1990), but did not distinguish between PAN and MPA. However, there are major differences between these two entities, as clarified and clearly established in definitions from the 1994 Chapel Hill nomenclature. PAN predominantly affects medium vessels, whereas MPA affects small vessels, especially arterioles, capillaries and venules. MPA is responsible for glomerulonephritis and lung capillaritis, while PAN is characterised by vascular nephropathy and never affects the lungs. ANCA are usually present in MPA and absent in PAN (Henegar et al, 2008).

4.3 Epidemiology

PAN is a rare disease that affects all racial groups. The HBV immunisation programmes and screening tests, as well as the changes in the classification of vasculitis and the better recognition of AAV as a separate identity, have resulted in a substantial reduction in the incidence of PAN. In Australia a small study reported a decrease in the temporal incidence of PAN: from 2.3 per million per year in the period of 1995–1999 to 1.1 per million per year in 2000–2004 (Ormerod and Cook, 2008). A study comparing the incidence of PAN in three European regions showed an annual incidence of 4.4–9.7 per million by the ACR criteria versus 0–0.9 per million by the Chapel Hill Consensus Conference (CHCC) definition (Watts et al, 2001).

PAN may be found in patients of all ages, including children and the elderly, but predominates in the 40–60-year-old age group. The male to female ratio is approximately equal.

4.4 Clinical features

4.4.1 General symptoms

A poor general condition is common. Weight loss and fever are present in two-thirds of patients (Pagnoux et al, 2010*). Symptoms occur early during the course of the disease and may be present at its onset. These symptoms can be isolated and the diagnosis is made only when other systemic manifestations occur. The characteristics of fever vary from one patient to another (high, remittent, with chills or intermittent).

4.4.2 Myalgias and arthralgias

Half of the patients have myalgias. These may be intense, diffuse, spontaneous or occur only after pressure is applied. Muscle enzymes are usually normal or slightly raised. Conversely, amyotrophy can be marked, but mostly reflects weight loss, sometimes of >20 kg, with some patients being bedridden owing to the intensity of pain and amyotrophy. Muscle biopsy can contribute decisively to the diagnosis of PAN when performed at this time. Arthralgias predominate in the knees, ankles, elbows and wrists, rather than the shoulders or hips. Synovitis is rarely seen and joints are usually not eroded nor deformed.

4.4.3 Neurological manifestations

Whereas peripheral neurological symptoms are frequent, CNS involvement is rare. Peripheral neuropathy is the most common finding in patients with PAN (50–75%), and in 23–33% is the earliest symptom of disease. Indeed, one of the variants of PAN exclusively involves peripheral nerve and muscle (Pagnoux and Guillevin, 2005b). Onset is usually acute, but may be more progressive, particularly in the elderly. Sensory signs are responsible for hypoaesthesia or hyperaesthesia, dysaesthesia or frank pain as the prominent and earliest features. Motor signs can occur thereafter. The first manifestations often affect the lower limbs, with one particular nerve involved. Later, other nerves become affected, with this pattern being referred to as mononeuritis multiplex. Indeed, mononeuritis multiplex affects 56.5–61.5% of patients. Mononeuritis (simplex) is less often seen. The pattern is usually distal and asymmetrical. The following nerves are preferentially involved: superficial peroneal, sural, radial, cubital and/or median nerves. In its late stage, so many nerves can be affected that mononeuritis multiplex can be mistaken for a symmetrical process. Cerebrospinal fluid, when analysed, is generally normal. Electromyography typically shows axonal neuropathy. Motor and sensory nerve action potential amplitudes are markedly decreased, or even absent, in the most severely affected nerves, while motor nerve conduction velocities are normal or only slightly diminished.

With treatment, mononeuritis multiplex in PAN progressively improves and patients may recover without sequelae. However, 12–18 months are often required before maximal recovery occurs. The degree of recovery is variable and unpredictable because, in some patients, severe neuropathy with extensive palsies may regress completely, whereas in others, minor palsies or sensory symptoms may never totally disappear. Sensory symptoms, usually paraesthesiae, persist longer and sometimes indefinitely. Moreover, several unpredictable peripheral neuropathy flares may occur.

CNS involvement (especially ischaemic, or more rarely haemorrhagic, stroke, seizure or confusion) is much less common and it is usually a late manifestation of the disease. Cranial nerve palsies are rare, being found in around 1% of patients with PAN, and affect the oculomotor (III), trochlear (IV), abducens (VI), facial (VII) and/or acoustic (VIII) cranial nerves. Vasculitis of the optic nerve, optic chiasm and/or occipital cortex has also been described. However, blurred vision or visual loss may also occur as a result of choroiditis, retinitis or brain parenchymal arteritis. The cerebrospinal fluid is usually normal but, in a few cases, an increased protein concentration, without increased cellularity, may be present.

4.4.4 Skin manifestations

Theoretically, cutaneous or subcutaneous nodules are the hallmarks of PAN, occurring in 8–27% of patients. They occur in clusters along the trajectories of superficial arteries and often disappear spontaneously within a few days, before new ones develop. Necrotic purpura is also common, and hence cannot be considered a

distinctive feature of MPA (Kluger et al, 2008). The main other differences between PAN and small vessel vasculitides are reported in table 6.

Ulcerations and livedo are less frequent. Local rupture of superficial arteries may lead to cutaneous haematoma or ecchymosis. A biopsy of infiltrated and/or central lesion zones can show vasculitis.

Other manifestations have been reported, such as bullous purpura and vesicles that may precede necrosis, urticaria, transient erythema or erythema annulare fugax, superficial phlebitis, Raynaud's phenomenon and splinter haemorrhages.

4.4.5 Renal manifestations

Renal artery involvement can be responsible for mild to severe and malignant arterial hypertension and/or vascular ischaemic nephropathy with renal insufficiency. Angiography, if performed, may show renal parenchymal infarcts and/or multiple stenoses and microaneurysms of branches of coeliac-mesenteric and/or renal arteries. Microaneurysms can occasionally rupture, spontaneously or after renal biopsy, which is therefore strongly contraindicated in the presence of microaneurysms. However, the main renal manifestation of AAV (glomerulonephritis) is never found in PAN; if this is reported on a biopsy, the diagnosis should be questioned because the patient actually has AAV.

4.4.6 Arterial hypertension

Hypertension is present in a mean of 40% of patients with PAN and is usually mild; however, it should be kept in mind that it can be triggered or adversely affected by glucocorticoids. Severe and malignant hypertension is detected in 4% of patients.

4.4.7 Cardiac manifestations

Cardiac involvement was reported with frequencies ranging from 10% in clinical investigations of patients with PAN to 40% when considering radiological and/or electrocardiographic anomalies, to 78% in a histopathological study.

Congestive heart failure is the main clinical feature, occurring in 6–57% of patients with PAN, but usually less often than in EGPA. Angiography can demonstrate coronary involvement in 85% of patients with clinical signs of infarction. In the remaining 15%, infarction may be due to arteritis in small coronary vessels or spasms.

Table 6 Main differences between polyarteritis nodosa (PAN) and ANCA-associated vasculitis

Disease characteristics	Polyarteritis nodosa	Microscopic polyangiitis	Eosinophilic granulomatosis with polyangiitis (Churg–Strauss)	Granulomatosis with polyangiitis (Wegener's)
Size of vessels predominantly involved	Medium	Small	Small	Small
ENT manifestation	No	Few patients, not specific, not destructive and not granulomatous	Allergic rhinitis, sinus polyposis (not destructive)	Frequent, crusting rhinitis, destructive sinusitis, saddle-nose deformity, nasal septum deformity, otitis media
Asthma	No	No	Yes (~100%)	No
Lung involvement	No (rarely, pleural effusion)	Frequent (60–80%), alveolar haemorrhage	Asthma in all. Frequent (50%), transient patchy infiltrates, eosinophil pleural effusion, rarely nodules	Frequent (60–80%), lung plain and/or excavated nodules, alveolar haemorrhage, bronchial and/or subglottic stenosis
Peripheral neuropathy (mononeuritis multiplex)	Very frequent (70%)	Frequent (35%)	Very frequent (65–75%)	Frequent (25%)
Kidney involvement	Reno-vascular involvement (hypertension, ischaemic renal lesions, 30–55%) but no glomerular disease	Very frequent, glomerulonephritis (necrotising extracapillary, 80%)	Not frequent, glomerulonephritis (necrotising extracapillary, 20%)	Frequent, glomerulonephritis (necrotising extracapillary, 70–80%)
Eosinophilia	No (or minor)	No (or minor)	Yes, often >3000/mm ³	No (or minor)
Microaneurysms on renal and/or coeliac angiography	Yes (65% of patients)	Rare (few case reports)	No	Rare (few case reports)
Granuloma on histology	Rare	Rare cases only	Yes, including eosinophils (frequent)	Yes (frequent but not always)
ANCA	No	Yes (60–80%), mainly anti-MPO	Yes (30–40%), mainly anti-MPO-ANCA	Yes (90% of those patients with systemic disease), mainly anti-PR3-ANCA
Relapse rate at 5 years (%)	<25	>50	>50	>60

ANCA, antineutrophil cytoplasmic antibodies; ENT, ear, nose and throat; MPO, myeloperoxidase; PR3, proteinase 3.

4.4.8 Aortic dissection and peripheral vascular manifestations

Aortic dissection is a rare complication, resulting from diffuse vasculitis of the aorta vasa vasorum. Dissection of other large arteries such as the carotid, hepatic, renal or splenic arteries, has also been reported. Peripheral arterial occlusions may be responsible for distal gangrene of the toes or fingers. Angiography can demonstrate the presence of stenoses and/or microaneurysms. Raynaud's phenomenon when present can remain isolated or be complicated by necrosis.

4.4.9 Gastrointestinal manifestations

GI tract involvement is one of the most severe manifestations of PAN, and is reported in 40–60% of patients, more often in HBV-related PAN (Pagnoux et al, 2005). GI manifestations are usually associated with other systemic manifestations of PAN, but they can be the first presenting signs in 2–16% of patients. They are the major cause of death within the first year after PAN onset, and thereafter are the third most common cause, just after infections and heart disease.

GI haemorrhages and small intestine perforations are the most feared manifestations, and are reported in 20–50% and 2–40% (mean 5%) of patients with PAN, respectively. When present, ischaemic vasculitis mainly affects the small bowel, and then, more rarely, the colon or stomach. In some cases, in the absence of disease manifestations, the diagnosis of vasculitis may be based on the histological findings after cholecystectomy or appendectomy. Patients with these localised GI forms usually have a good prognosis after prompt combined medical and surgical treatment. By contrast, acute necrotising or, less commonly, chronic pancreatitis, sometimes with pseudo-cysts, carries an extremely poor prognosis, because of the regular association with severe small intestine ischaemia and/or perforations. However, its incidence is low (seen in about 2–3% of patients).

Digestive malabsorption and exudative enteropathy have been reported on rare occasions. The liver and spleen can be involved, even in the absence of HBV infection, with infarct(s) and/or haematoma(s).

4.4.10 Orchitis

Orchitis is one of the most characteristic manifestations of PAN and was retained as one of the classification criteria established by the ACR. When treated immediately with glucocorticoids, orchitis may regress. In other cases, the ischaemia can be irreversible.

4.4.11 Pulmonary manifestations

The lungs are spared in PAN, in contrast to other vasculitides, such as MPA, EGPA or GPA. When pulmonary symptoms occur, infection should be looked for first, and is usually found.

4.4.12 Bone manifestations

Periosteal changes can be seen, which develop mainly in the legs. Localised oedema and pain are common symptoms. A few cases of bone necrosis have also been reported.

4.4.13 Ophthalmological signs

The eye can be affected in PAN, sometimes severely, as with unilateral or bilateral choroiditis, iritis, iridocyclitis, retinal detachment and/or retinal vasculitis

4.4.14 Localised forms of polyarteritis

Cutaneous PAN (cPAN) is relatively common, as opposed to other types of localised polyarteritis. In 1931 it was described as a distinct entity separate from systemic PAN, limited to the skin, adjacent muscles, nerves and joints. cPAN does not have any specific criteria; its diagnosis is based on clinical and histopathological findings. It has a more favourable prognosis, but relapses are very frequent. Evolution of cPAN into systemic PAN is possible but rare, patients should be kept under regular follow-up (Furukawa, 2012).

Isolated involvement of one skeletal muscle or a muscle group, and isolated neuropathy (mononeuritis multiplex or simplex) without systemic symptoms, have been described, such as occasional cases involving only one organ—the appendix, gallbladder, testis, breast or uterus. These forms usually also have good prognoses.

4.4.15 PAN in childhood

PAN is the third most common childhood vasculitis, after Kawasaki disease and IgA vasculitis (Henoch–Schönlein) (Ozen et al, 2006*). It is associated with fewer relapses and less mortality than adult PAN. In a review of 110 children who had been diagnosed with PAN, 30% were classified as cPAN, 57% as systemic PAN, 8% as MPA associated with ANCA and only 5% had classic PAN associated with hepatitis B surface antigen (Ozen et al, 2004).

4.5 Laboratory tests and angiographic investigations

4.5.1 Laboratory findings

Inflammatory features are found in the majority of patients. An erythrocyte sedimentation rate >60 mm during the first hour (78–89% of patients), raised C-reactive protein, raised white blood cell count (45–75% of patients) and normochromic anaemia (34–79% of patients) are common laboratory findings. Sometimes, a slightly raised eosinophil count of up to 1500/mm³ can be seen. The presence of HBsAg should be systematically sought. Unlike classic PAN, hypocomplementaemia can be found in patients with HBV-associated PAN.

ANCA are supposedly negative in PAN and if present should really challenge the diagnosis. The presence of ANCA giving a cytoplasmic or perinuclear labelling pattern, primarily directed against myeloperoxidase (anti-MPO) in ELISA, should be taken as an argument in favour of MPA rather than PAN.

4.5.2 Angiography

Medium-size arterial stenoses and microaneurysms can be seen on coeliac-mesenteric and renal angiography in PAN. Arterial saccular or fusiform aneurysms range in size from 1 to 5 mm and are predominantly seen in kidneys, mesentery and liver (figure 24). Less often, involvement of lumbar and intercostal arteries can also occur (figure 25). The lesions may disappear with effective vasculitis therapy. Although microaneurysms are not pathognomonic, they are commonly present (>60% of patients) in PAN. Conversely, they can be seen in endocarditis or artery fibrodysplasia, and, very rarely, in ANCA-associated vasculitides. Although conventional angiography still remains the 'gold standard' for detecting microaneurysms (having a higher sensitivity for their detection), because of its associated morbidity, CT or magnetic resonance angiography are now more commonly used in daily practice.

Figure 24 Renal angiography showing multiple microaneurysms in a patient with polyarteritis nodosa.

Figure 25 Angiogram of a 27-year-old woman with polyarteritis nodosa showing aneurysms of the intercostal arteries.

4.6 Histopathology

The histological lesion defining PAN is focal segmental necrotising vasculitis of medium arteries, less commonly arterioles, and only rarely, and not predominantly, capillaries and venules. The lesion may occur in any artery of the body, but involvement of the aorta and/or other large elastic arteries and/or pulmonary arteries has been described very rarely. The acute phase of arterial wall inflammation is characterised by fibrinoid necrosis of the media and an intense pleomorphic cellular infiltration, with predominantly neutrophils and variable numbers of lymphocytes and eosinophils. The normal architecture of the vessel wall, including the elastic laminae, appears to be completely disrupted and/or erased, and replaced by a band of amorphous eosinophilic material, resembling fibrin when stained. Arterial aneurysms and thromboses can occur at the site of the lesion. Arterial healing is characterised by fibrotic endarteritis that may lead to aneurysm regression or, when too abundant, to vessel occlusion. One of the characteristic histological features of PAN is the coexistence of necrotising vasculitis and a healed lesion or normal arteries in different tissues or in different parts of the same tissue.

Several potential biopsy sites can be diagnostic for PAN. Biopsies of the skin nodules are the most effective, enabling diagnosis in 95% of cases (dropping to 50% once they ulcerate). In patients with myalgias with or without concomitant mononeuritis multiplex, or presenting with general symptoms, a muscle biopsy is often useful. It should be performed at the myalgia site or in the gastrocnemius or peroneal muscles. The sensitivity of biopsies performed in proximal muscles (deltoid or quadriceps) is lower than in distal muscles. Nerve biopsy

in a sensory branch of the sciatic peroneal nerve can also be performed when the patient has distal mononeuritis multiplex in its sensory or motor-sensory form, with a sensitivity of about 50%. When patients do not have sensory signs in a candidate region for biopsy, the results have low sensitivity. Nerve biopsy can often prove the presence of vasculitis but cannot easily provide a diagnosis of PAN (vs MPA or other small vessel vasculitis) because nerve arteries are usually small. Furthermore, the biopsy itself can cause a permanent sensory deficit. Because renal involvement results from ischaemia, and not glomerular endothelium involvement, and because of the risk of haematoma due to traumatic rupture of a microaneurysm, renal biopsy is not relevant or recommended in cases of suspected PAN. Occasionally, temporal artery biopsy can show necrotising vasculitis, a histological finding that is rather uncommon in typical giant cell arteritis but has been seen in a few patients with AAV.

4.7 Aetiology and pathogenesis

The aetiology remains elusive for most patients. Nevertheless, in a few cases, infections, mainly viral, have been recognised as being responsible for PAN. Although viral antigens or immune complexes have rarely been found in the vessel walls of patients with PAN, a close relationship has been demonstrated between PAN and HBV infection. HBV infection through contaminated blood transfusion has now almost disappeared, with intravenous drug abuse and sexual transmission of HBV now the major causes of HBV-related PAN. The development of vaccines against HBV and their administration to those at risk, as well as the increased safety of blood transfusions, explain the dramatic decrease of the number of new cases seen since 1989. The frequency of HBV infection fell from 38.5% during 1972–1976 to 17.4% during 1997–2002, with a peak of 48.8% between 1982 and 1986. Over the past few years, the frequency of HBV-related PAN has declined to 20% (Pagnoux et al, 2010*).

Some other viruses have also been associated with PAN, but only explain a small number of cases. A few cases associated with hepatitis C virus (HCV) or parvovirus B19 infections have been described. Other viruses have been incriminated in PAN, and there are anecdotal reports of human immunodeficiency virus infections. Herpes zoster can also be responsible for vasculitis, like some members of the Herpes viridae family.

In addition to infectious causes, PAN-like disease has been described in association with malignancies. The closest relationship has been established with hairy-cell leukaemia. Malignancies are, for the most part, associated with small vessel vasculitides and very few cases of malignancies in true PAN have been reported.

Hence, the immunopathogenic mechanisms leading to vascular injury in PAN are probably heterogeneous. To date, there is no reliable animal model of the disease. The PAN-like disease in cynomolgus macaques, which is similar to the human disease, occurs only sporadically. The mechanism of vascular inflammation implicated most often, based on animal models but also some human studies (Trepo and Guillevin, 2001), is an immune-complex induced lesion. Pertinently, almost all cases of HBV-related PAN are associated with wild-type HBV,

HBe antigenaemia and high HBV replication, supporting the concept that lesions may result from the deposition of soluble viral antigen (Ag)–antibody (Ab) complexes in Ag excess, possibly involving surface antigen (HBsAg) and/or HBeAg. According to this hypothesis, immune complexes would activate the complement cascade, whose activated products would, in turn, attract and activate neutrophils. However, no recent study has explored the pathogenic mechanisms of PAN unrelated to HBV, which remain largely unexplained.

4.8 Treatment of PAN

4.8.1 Treatment of HBV-related PAN

In chronic hepatitis B, glucocorticoids and immunosuppressive agents have deleterious effects and enhance viral replication, despite having proved to be beneficial against the symptoms of vasculitis. Over the long term they perpetuate chronic HBV infection and facilitate progression towards cirrhosis, which may be complicated later by hepatocellular carcinomas.

Thus, the duration of glucocorticoid use must be short to rapidly control the most severe life-threatening manifestations of PAN, which are common during the first weeks of the disease. Glucocorticoids must then be abruptly stopped after 2–4 weeks to enhance immunological clearance of HBV-infected hepatocytes and favour HBeAg to anti-HBeAb seroconversion. The second part of the treatment consists of plasma exchange to clear circulating immune complexes and is usually prescribed until HBeAg to anti-HBeAb seroconversion is achieved. Antiviral agents must also be given to control viral replication as the third part of the treatment, beginning in the first weeks. At present, a combination of antiviral agents (e.g., tenofovir and/or entecavir) is best, using interferon α 2b, lamivudine and/or other newer antiviral drugs (Guillevin et al, 2005; Pagnoux et al, 2006). Owing to the rarity of the disease now, no study will be able to determine which antiviral combination is the most efficient, but therapeutic advances in chronic HBV infection can probably be transposed to HBV-related PAN.

Treatment for other virus-related PAN should also rely on the combination of short courses of glucocorticoid therapy and antiviral agents, together with plasma exchange when manifestations are severe. For HCV-related vasculitis, RTX should be considered, as suggested for the treatment of HCV-associated cryoglobulinaemic vasculitis (Saadoun et al, 2010). PAN associated with parvovirus B19 can respond to intravenous immunoglobulin therapy.

4.8.2 Treatment of non-viral PAN

In PAN, and in AAV, it seems reasonable to adapt the initial treatment to the severity of the vasculitis and not to systematically propose a standard treatment. To help the clinicians choose the most effective treatment, the FFS and BVAS should be used (see AAV treatment, section 3.4).

No robust data is available supporting the use of plasmapheresis in non-viral PAN, regardless of its prognosis; however, it may be useful in refractory PAN (Puéchal and Guillevin, 2013; de Luna et al, 2015).

After successful induction of disease remission in severe diseases, the switch from CYC to AZA or MTX is extrapolated from the AAV maintenance regimens; there are still no consistent data available for use of these drugs for PAN (de Menthon and Mahr, 2011).

Few data are available for the treatment of cPAN. Mild cases may resolve with non-steroidal anti-inflammatory drugs or colchicine; however, if ineffective, treatment with systemic glucocorticoids (0.5–mg/kg/day of oral prednisone or equivalent) and other drugs, such as dapsone or hydroxychloroquine, may help to achieve adequate responses. AZA, MTX and CYC are reserved for more severe cases unresponsive to glucocorticoid therapy (de Menthon and Mahr, 2011). In addition, there have been some reports of patients resistant to systemic glucocorticoids and immunosuppressive therapy successfully treated with IVIg or infliximab (Vega Gutierrez et al, 2007; Lobo et al, 2008).

In childhood PAN, there is a current randomised controlled trial comparing MMF with CYC for the induction treatment of the disease (MYPAN, ClinicalTrials.gov identifier: NCT00414128). It is the first randomised controlled trial examining the treatment of systemic PAN. Biological agents, such as infliximab, adalimumab, etanercept and rituximab, have also been explored (Eleftheriou et al, 2009).

4.9 Outcome and prognosis of PAN

In its systemic form, PAN is an acute disease, which can be severe and cause death if timely adequate treatment is not implemented. In historical series, only about 13% of untreated patients survived. Since the introduction of glucocorticoids, and their later combination with immunosuppressant agent(s), antiviral therapy for HBV-related PAN and plasma exchange, when appropriate, the prognosis of PAN has improved and overall survival rates have increased to more than 76–89% for PAN and 64–70% for HBV-related PAN (Guillevin et al, 1996). Although treatment can now control the outcome for most patients, some relapse and/or die of disease-related or treatment-related causes.

4.9.1 Relapses

Once remission has been obtained, PAN recurs much less frequently than other systemic vasculitides. In a study of 348 patients with a mean follow-up exceeding 5 years, 11% of patients with HBV-related PAN and 28% of those with non-HBV-related PAN relapsed, with mean times to first relapse of 43 and 26 months, respectively (Pagnoux et al, 2010*).

4.9.2 Deaths

In the above study of 348 patients with PAN, overall mortality was 25% after 5 years (20% for non-HBV-related PAN versus 34% for HBV-related PAN), with age >65 years, hypertension and abdominal surgery being independent predictors of death (Pagnoux et al, 2010*). In addition, the presence of any of the factors from the FFS indicates higher mortality rates: when FFS was 0, mortality at 5 years was 12%, when FFS was 1, mortality was 26%, and when FFS was ≥ 2 , mortality was 46%.

Although the causes of death vary from one vasculitis to the other, they can be divided into two categories: deaths attributable to the vasculitic process and those due to treatment side effects, with infections favoured by glucocorticoids and/or cytotoxic agents being one of the leading causes of death.

A few patients die during the first months of the disease from multivisceral involvement often caused by uncontrolled vasculitis because treatment cannot control the disease (Bourgarit et al, 2005). Typically, death occurs during the course of disease characterised by fever, rapid weight loss, diffuse pains and one or several major organ involvement. For PAN, deaths are often the consequence of GI involvement.

The deaths occurring in the following years may be the consequence of treatment side effects. These adverse events emphasise the importance of tailoring the therapeutic regimen after careful analysis of parameters predictive of outcome, such as those included in the FFS (Guillevin et al, 1996).

SUMMARY POINTS

- Granulomatosis with polyangiitis (GPA) (Wegener's), microscopic polyangiitis (MPA) and eosinophilic GPA (Churg–Strauss) are primary necrotising vasculitides of small vessels, which can be defined using the Chapel Hill nomenclature and are associated in many patients with the presence of antineutrophil cytoplasmic antibodies (ANCA).
- Patients with GPA (Wegener's) can have a systemic generalised form of the disease associated with cANCA positivity with proteinase 3 specificity (but not exclusively) or a more localised form associated with ANCA in only about 50–75% of cases. Progression from one form to the other is possible throughout the disease, with persistently localised disease being rare (<5% of all patients).
- MPA is associated with pANCA to myeloperoxidase (MPO) in nearly 75% of cases.
- Treatment for GPA (Wegener's) and MPA relies on a combination of glucocorticoids and immunosuppressant agents (i.e., intravenous cyclophosphamide pulses or continuous oral cyclophosphamide or rituximab) for induction therapy, followed by a maintenance regimen with glucocorticoids and another less toxic immunosuppressant agent, such as rituximab, azathioprine or methotrexate, for a total duration of treatment of not less than 18 months.
- Rituximab is a newer and non-inferior alternative to cyclophosphamide for inducing remission in patients with generalized GPA (Wegener's) or severe forms of MPA and is superior to AZA as maintenance treatment.
- Despite staged induction–maintenance treatment, the relapse rate remains as high as 35% at 3 years for GPA (Wegener's), being slightly lower for MPA. The identification of parameters predictive of relapse might in the future help treatment to be adjusted according to the characteristics of individual patients. The identification of new strategies and new agents may also help to further improve patient outcomes.
- Eosinophilic GPA (Churg–Strauss) is associated with ANCA, mainly pANCA to anti-MPO, in only 30–40% of patients, and there are some clinical differences according to their presence or not, suggesting that distinct pathogenic mechanisms may be involved, such as ANCA and/or eosinophil-mediated cytotoxicity.
- Treatment for patients with eosinophilic GPA (Churg–Strauss syndrome) without poor prognostic factors can consist of glucocorticoids alone, whereas those with at least one poor prognostic factor according to the Five-Factor Score must receive a combination of glucocorticoids and immunosuppressant agent. Mepolizumab has been demonstrated to provide a better control of the asthmatic and ENT manifestations once vasculitis remission has been achieved but its effect on vasculitis remains uncertain.
- Polyarteritis nodosa (PAN) is a medium vessel systemic necrotising vasculitis. Its frequency has dramatically decreased during the past two decades, in parallel with that of hepatitis B infection (HBV).
- Patients with HBV-related PAN must receive a short course of glucocorticoids to control the vasculitic manifestations, antiviral agents and plasma exchange. Patients without HBV infection should receive glucocorticoids systematically, in combination with an immunosuppressant agent, mainly cyclophosphamide, when poor prognostic factors are present.

IN-DEPTH DISCUSSION I

**Assessment of disease activity and damage in small and
medium vessel vasculitis**

I introduction

There are no universally applicable serological markers to assess disease activity or determine chronic sequelae in most forms of vasculitis. Inflammatory markers such as CRP and ESR are not specific to vasculitis; although they are useful additional test when determining disease activity, they are also affected by other causes especially infection, which may mimic vasculitis or co-exist in patients with established vasculitis. Rising ANCA titres using highly sensitive new capture and anchor ELISA methods may prove to be of clinical relevance in predicting relapse, but this technology is still in its infancy and cannot yet be recommended in this setting (Roggenbuck et al, 2009). Furthermore, rising titres may occur in up to 40% of patients who do not subsequently demonstrate any change in clinical features to suggest reactivation of disease. Imaging modalities which can guide disease activity in large vessel vasculitis such as PET scanning are not useful in small vessel vasculitis. Instead, the best current method of determining disease activity and measuring chronic damage is to use clinical tools developed and validated for this purpose. Their main role is to guide treatment decisions, but they can also be of great value in clinical studies as outcome measures and to record the natural history of disease. We will review the concepts of disease activity and disease damage and provide an overview of the clinical tools available.

II Disease activity

The European League Against Rheumatism (EULAR) recommends the use of the Birmingham Vasculitis Activity Score (BVAS) to standardise the assessment of disease activity in clinical trials involving the systemic vasculitides (Hellmich et al, 2007; Yates et al, 2016). The BVAS has largely superseded the use of other scales of activity such as the Groningen Index (Kallenberg et al, 1990) the Disease Extent Index (DEI) (De Groot et al, 2001) and the Vasculitis Activity Index (VAI) (Whiting-O'Keefe et al, 1999) which are described in Table 1, but are not discussed further.

BVAS formalised the assessment of active vasculitis in one section for general features (systemic) and eight specific organ systems: cutaneous, mucous membranes/eyes, ear, nose and throat, chest, cardiovascular, abdominal, renal, and neurological (Luqmani et al, 1994). Symptoms and signs of organ involvement were recorded only if they could be attributed to new or worsening features of vasculitis and not another cause such as infection or side effects from medications. The items were designed to be easy to determine through taking a history and performing a standard examination of the patient together with a few simple investigations such as urinalysis and serum creatinine (Luqmani et al, 1994). Plain chest radiographs are recommended at first assessment of most patients with vasculitis as part of standard care, but do not need repeating at each visit unless clinically indicated. Repeat biopsies which had been required in the previous Groningen Index of activity in patients with granulomatosis with polyangiitis (Wegener's; GPA) (Kallenberg et al, 1990) were excluded on ethical and practical grounds. We tested the BVAS on 213 consecutive patients

with different types of vasculitis. BVAS was feasible to use and had content validity (comprehensiveness) and face validity (credibility) when trialled by a group of physicians with expertise in vasculitis. The BVAS also made biological sense (construct validity) when measured against other scores of disease activity and was sensitive to change when measured serially in 30 patients observed during episodes of both disease activity and inactivity (Luqmani et al, 1994). The BVAS score was weighted (by physician driven consensus) more towards items representing objective evidence of organ involvement, (e.g. significant rise in serum creatinine) as opposed to more subjective and less organ threatening symptoms (e.g. arthralgia) (Luqmani et al, 1994).

The design of the BVAS evolved through its use by the European Union Study Group of Therapeutic Trials in Systemic Vasculitis (ECSYSVASTRIAL) in clinical studies (Luqmani et al, 1997). Minor adjustments were made to the items included and for the first time the presence of persistent, low-grade disease, i.e. not new or worse but grumbling activity was recorded separately, as were the results of specialist opinions from ENT, cardiology or ophthalmologists (Luqmani et al, 1997). The BVAS has been used in several large clinical trials to assess disease activity and define remission and relapse (De Groot et al, 2009; De Groot et al, 2005; Jayne et al, 2003; Jayne et al, 2007). The latest version of BVAS (v.3) has further optimised the items included, excluding items with low specificity for vasculitis and grouping those due to the same pathological processes under the same headings (Flossmann et al, 2007; Suppiah et al, 2011). A single box for “persistent only disease” has replaced the second column to record ongoing active features to simplify the scoring system (Flossmann et al, 2007). Initial variation in scores between different physicians highlighted the need for adequate training to ensure that only items due to active vasculitis (rather than from infection or previous damage) are scored (Flossmann et al, 2007). The BVAS (v.3) forms, training manual and glossary sheet are available online at the EUVAS website (<http://www.vasculitis.org>). The BVAS (v.3) has been validated for assessment of activity of patients with systemic vasculitis, is reproducible and sensitive to change and demonstrates convergence with CRP, physician global assessment and treatment decisions (Mukhtyar et al, 2009). The BVAS has also been adapted for use in trials involving only patients with GPA (BVAS/WG) by concentrating on clinical features specific for patients with GPA (e.g. subglottic involvement) and excluding items less relevant to GPA (e.g. bruits or loss of pulses) (Stone et al, 2001). The BVAS/WG index has been validated in simulation exercises and actual patients with GPA, is sensitive to change with good inter and intra-observer reliability and correlates with the physician’s global assessment (Stone et al, 2001). An exercise applying different assessment tools to paper cases with GPA and microscopic polyangiitis, found a high correlation in scores between the BVAS/WG, BVAS, Physician global assessment and the DEI (Merkel et al, 2009). The BVAS/WG is not recommended for use in non-GPA vasculitis patients because it is yet to be clinically validated in this group.

III Disease Damage

The principle of disease damage in vasculitis is to measure chronic changes or scarring that has resulted since a diagnosis of vasculitis was made. The cause of the damage is not considered to be as important as the fact that

the patient has developed damage. Clearly for some features, the vasculitis itself, or its treatment are responsible. In other cases, co-morbidity from chronic disease or from an aging population is the cause. The most important aspect of recording damage in patients with vasculitis is that we actually ignore causation and only focus on the damage item itself. By definition, damage can only occur after the onset of vasculitis, and represents “permanent” effects (permanence is carefully defined in this context as an item that has lasted at least 3 months, or in the case of a single event, has occurred at least 3 months prior to the current assessment), even though the actual problem may have resolved (e.g. a myocardial infarction, from which the patient has made an apparent full recovery still represents permanent scarring in the myocardium). One of the important concepts of damage is to recognise components of disease that will not respond to immunosuppressive treatment and therefore, by categorising the item as damage, this should prevent inappropriate use of potentially harmful therapy. The concept is intuitive, but for accuracy, reproducibility and to monitor change over time we need an easy and well-defined method of measuring damage. The Vasculitis Damage Index (VDI) is the most widely used and validated method, and recently compared very favourably to a newer tool called the Combined Damage Assessment index (CDA) (Suppiah et al, 2011). An older damage tool called the Systemic Necrotising Vasculitis (SNV) damage index is summarised in Table 1, but it is no longer used and therefore not discussed further (Abu-Shakra et al, 1994). The other tool that is sometimes considered in this category is the five-factor score (FFS) which was proposed by the French Vasculitis Study Group, but this is a prognostic score rather than a detailed damage assessment (Guillemin et al, 1996).

IV Vasculitis Damage Index

The VDI is a generic tool created by the Birmingham Vasculitis Group (UK) in 1997 and is designed to be used with all types of systemic vasculitis (Exley et al, 1997). The principles guiding damage assessment, the items included and the glossary of terms for the VDI were developed by consensus of experts in vasculitis. The VDI comprises 64 items grouped into 11 organ systems. An arbitrary time limit of ≥ 3 months is used as the cut off for scoring an item of damage. For consistency, items such as stroke or myocardial infarction which are discrete events are still only scored after 3 months from the initial episode. Each item is scored as present or absent irrespective of the underlying cause as long as it has occurred after the onset of vasculitis. The intention is to capture damage due to disease or treatment but it is possible that other problems relating to an ageing population contribute to an increasing VDI score over time. There is no weighting of items; each item scored as present counts towards the total score (maximum possible = 64). Several groups have shown that the VDI score is an important prognostic marker (Koldingsnes et al, 2002; Exley et al, 1997). A score ≥ 1 on the VDI at time of first starting immunosuppression is a predictor of higher mortality [HR 6.1 (95% CI 1.7-22.1)] in GPA (Koldingsnes et al, 2002). A score of ≥ 5 at 6 months in a cohort of mixed primary and secondary vasculitis showed a much higher risk of mortality by 2 years [HR 12.3 (95% CI 4.2-36.9)] (Exley et al, 1997). Studies using the VDI have shown that the greatest accumulation of damage occurs in the first 6 months following a

diagnosis of vasculitis (Koldingsnes et al, 2002; Exley et al, 1997). The VDI has been used as an outcome measure in most of the major clinical trials in ANCA associated vasculitis over the past decade (De Groot et al, 2009; De Groot et al, 2005; Jayne et al, 2003; Jayne et al, 2007; WGET, 2005).

V Combined Damage Assessment

The ANCA-associated Vasculitis Instrument of Damage (AVID) is currently being assessed against the VDI in the RAVE trial (Rituximab for ANCA associated Vasculitis Trial); although initial RAVE results have been published, the results of the comparison of damage indices are not yet published. At the same time, we have revised the VDI to be more specific for ANCA-associated vasculitis. Considerable overlap was noted between the 2 separate efforts and therefore the group decided to merge both projects to create a new tool, the Combined Damage Assessment index (CDA).

The CDA comprises 135 items grouped into 17 categories; includes laterality for damage to the eyes and ears and records gradation of severity for 8 items (Seo et al, 2007). The extra components (e.g. striae, easy bruising and weight gain) in the CDA (compared to the VDI) derive from information previously recorded in the 'other' category on the VDI for patients enrolled in the WGET trial (Seo et al, 2005) and also distinguishes between left and right for damage to the eyes and ears (Seo et al, 2007). A survey of 50 experts in vasculitis covering all relevant specialties has shown that malignancy, renal failure, severe respiratory compromise, cardiovascular disease and blindness should have the greatest importance whereas items such as muscle atrophy, bruising, mouth ulcers, striae and alopecia should have the lowest (Seo et al, 2009). The other difference between the CDA and the VDI are that the time cut off for damage is defined as ≥ 6 months and the item of damage must be attributable to vasculitis or its treatment. A recent study has compared the CDA to the VDI in a cross sectional study of 285 patients with primary and secondary causes of vasculitis; the majority of patients (70%) had ANCA associated vasculitis. Attribution to cause of damage was not applied and the ≥ 3 -month time point was used for both the VDI and CDA. The findings were that although the CDA was more sensitive at detecting damage, it was more time consuming and had lower inter- and intra-observer reliability than the VDI due to its complexity (Suppiah et al, 2011).

VI Functional assessment

With improvement in immunosuppressive therapy for the treatment of systemic vasculitis, patients are now surviving for longer, but the effect of pain and other disease symptoms can result in significant impairment to their function and quality of life (Koutantji et al, 2003). Self-reported assessment tools to measure quality of life such as the SF-36), and the HAQ to measure levels of physical functioning and disability are established for use in patients with chronic disease and have been used in patients with vasculitis (Koutantji et al, 2003; Hoffman et al, 1998; Pincus et al, 1999; Walsh et al, 1999).

The OMERACT Vasculitis Working Group has recognised that developing vasculitis- specific patient reported outcome measures (PROMs) is an essential area for future research, because generic tools such as the SF-36 may not be precise enough to accurately measure change in this set of chronic complex multisystem diseases (Merkel et al, 2009).

VII Conclusion

There is no gold standard for assessment of disease activity and damage in patients with systemic vasculitis. However, current methods have been important in standardising the approach to individual patients and also been the cornerstone of the assessment and treatment decisions in many recent clinical trials in vasculitis. These tools will always be imperfect and need ongoing review and revision. Nevertheless, their use is recommended and endorsed by OMERACT (Merkel et al, 2011). In future, new biomarkers may be incorporated into, or surpass these instruments. Emerging issues are the patient perspective in these chronic relapsing diseases; so far little attention has been paid to this area, but it is increasingly apparent that issues which are important to physicians are not the same as the issues considered most important to patients.

Table 1: Summary of Vasculitis Assessment tools.

Assessment tool	Description	Comments	Reference
Disease activity tools			
Groningen Index	Scored on clinical signs and histology.	Impractical for serial assessment because it requires repeat biopsies to provide histological evidence of activity, developed in GPA.	Kallenberg <i>et al</i> , 1990
Vasculitis Activity Index (VAI)	Nine rating scales for separate organ system involvement (graded 0-4) combined with laboratory tests.	Easy to complete but highly subjective.	Whiting-O'Keefe <i>et al</i> , 1999
Disease Extent Index (DEI)	Signs and symptoms, and diagnostic procedures to be performed to confirm active vasculitis in 10 organ systems (each scoring 2) plus constitutional symptoms (scores 1).	Assessment of current damage and activity, designed for use in WG. Weighting used.	De Groot <i>et al</i> , 2001
Birmingham Vasculitis Score (BVAS)	9 organ based systems. Physician consensus derived weighting for each individual item and maximum totals applied to each system.	Physician must decide if items due to new or worse active vasculitis; persistent disease could be documented in the later version but increases complexity of evaluation.	Luqmani <i>et al</i> , 1994; Luqmani <i>et al</i> , 1997

BVAS (v. 3)	66 clinical features grouped into nine organ systems. Weighting according to perceived clinical relevance. Inclusion of some items requiring specialist opinion or further tests.	Physician must decide if items due to active vasculitis, persistent disease indicated by single box (only if all items are persistent).	Mukhtyar <i>et al</i> , 2009
BVAS/WG	Addition of “other section” to nine organ systems used in BVAS. 34 separate disease items, chosen as more specific for GPA, further classified into major (organ- or life- threatening) or minor items.	Only validated for use in GPA although shown to correlate with BVAS for other vasculitides.	Stone <i>et al</i> , 2001

Damage assessment tools

Systemic necrotizing Vasculitis (SNV) Damage Index	34 items. Scoring occurs if damage present for ≥6 months except for irreversible items such as stroke and myocardial infarction which are scored immediately. Some items have double weighting. Does not include items of damage in the ENT system.	Superseded by VDI.	Abu-Shakra <i>et al</i> , 1994
Vasculitis Damage Index (VDI)	Generic tool for all types of vasculitis. 64 items grouped into 11 organ systems. No weighting of items in current version.	1 page tool, easy to use. Validated and widely used.	Exley <i>et al</i> , 1997
ANCA Vasculitis Index of Damage (AVID)	Specific for ANCA associated vasculitis. Left and right sides scored separately for damage to eyes and ears.	Undergoing validation.	Seo <i>et al</i> , 2007
Combined Damage Assessment index (CDA)	Specific for ANCA associated vasculitis. 135 items in 17 organ systems. Left and right side scored separately for damage to eyes and ears. Weighting of items is planned for the future.	Shown to be inferior to VDI.	Seo <i>et al</i> , 2007; Suppiah <i>et al</i> , 2011

Prognostic tools

Five factor score (FFS)	Prognostic factors in polyarteritis nodosa (PAN), microscopic polyangiitis (MPA) and eosinophilic GPA (Churg-Strauss). The parameters of the original FFS are: renal failure, proteinuria, cardiomyopathy, GI tract and CNS involvement. The revised FFS allows also identification of prognostic factors in GPA patients. It includes age >65 years as another measure of poor prognosis and the presence of ENT manifestations as a parameter of good prognosis in GPA and EGPA.	FFS=0, 5 year mortality 11.9%; FFS=1, 5 year mortality 25.9%; FFS>2, 5 year mortality 45.95%.	Guillevin <i>et al</i> , 1996; Guillevin <i>et al</i> , 2011 for revisited version
Vasculitis Damage Index (VDI)	Several studies have shown that the VDI score at different time points can be an important prognostic marker for future death and morbidity.	A VDI score ≥ 5 at the 6 month time point has a HR of 12 for death at 2 years compared to those with a lower score.	Exley 1 <i>et al</i> , 1997

Functional assessment tools (No vasculitis specific tools currently available)

Health Assessment Questionnaire (HAQ)	Self-assessment form to measure levels of physical functioning and disability.	Designed for use in RA, now generic use as tool in chronic diseases.	Pincus <i>et al</i> , 1999; Koutantji <i>et al</i> , 2003
Short form 36 (SF-36)	Self-assessment generic measure of health status. 36 questions. Dimensions: physical function, role limitation (physical or emotional), mental health, social functioning, energy, pain and perception of general health.	Generic use in chronic disease.	Hoffman <i>et al</i> , 1998; Koutantji <i>et al</i> , 2003

The BVAS, BVAS (v.3) and the VDI forms, training manual and glossary sheets are available online on the EUVAS website (<http://www.vasculitis.org/>).

IN-DEPTH DISCUSSION II

The role of biologics in ANCA-associated vasculitis

INTRODUCTION

In this in-depth discussion we review the role of biologics in the treatment of ANCA associated vasculitides (AAV), and the therapeutic developments expected to occur in the near future.

GRANULOMATOSIS WITH POLYANGIITIS (GPA) and MICROSCOPIC POLYANGIITIS (MPA)

Rituximab

Rituximab (RTX) is a chimeric monoclonal antibody against CD20, a receptor found on the membrane of mature B cells. Many arguments support the use of anti-B-cell drugs in AAV. RTX has been shown to be useful in induction and maintenance of remission in generalised GPA and severe MPA patients.

Two randomized controlled trials (RCT) pointed out the non-inferiority of RTX in inducing remission compared with cyclophosphamide (Stone et al, 2010; Jones et al, 2010). The remission rates were not different in the 2 treatment groups and the short term safety profile was similar, leading to its registration by the EMA and FDA in those patients. In addition, rituximab was found to be superior to conventional induction therapy in relapsing patients (Stone et al, 2010) and may also be effective in refractory disease after failure of induction treatment (Miloslavsky et al, AR 2013). Rituximab should be preferred for women of child bearing age. A recent retrospective study has shown that the malignancy risk in patients with AAV was lower in RTX-treated patients than in cyclophosphamide-treated patients (van Daalen et al, 2017).

Furthermore, RTX has changed the standard of care for maintenance therapy in those patients. RTX superiority to azathioprine to maintain remission was demonstrated in a study comparing pre-emptive low dose RTX with azathioprine after remission achieved with a combination of cyclophosphamide and glucocorticoids (Guillevin et al, 2014). Overall, 57 patients received RTX maintenance re-treatment every 6 months (500 mg RTX, five infusions over 18 months) and 58 patients were treated with AZA (starting at 2 mg/kg/day). The primary end point was the rate of major relapses at 28 months: major relapse had occurred in 3 patients in the RTX group (5%) and in 17 patients in the azathioprine group (29%) ($P=0.002$). The frequencies of severe adverse events were similar in the two groups. At month 60, major-relapse-free survival rates were 71.9% and 49.4% ($P=0.003$); minor-and-major relapse-free survival rates were 57.9% and 37.2% ($P=0.012$); and cumulative glucocorticoid use was comparable (Terrier et al, 2018).

The best treatment schedule (RTX injection on demand or driven by surrogate markers such as CD19 level and/or ANCA titer), and its duration are being investigated in 2 RCT. The former has compared two RTX regimens: 500 mg infusions according to ANCA status/titer and/or circulating CD19 B-cell reappearance versus systematic 500

mg infusions at fixed intervals of 6 months (controls) (Charles et al, 2018). AAV relapse rates for patients given individually tailored or systematic RTX-infusion schedules did not differ significantly. However, the experimental arm patients received fewer infusions and lower total RTX doses. The objective of the latter ongoing trial is to determine the optimal duration of the RTX maintenance treatment to prevent relapses (2 or 4 years) (ClinicalTrials.gov identifier: NCT02433522).

In addition, RITAZAREM is comparing a different RTX regimen (1 g every 4 months until month 20) with AZA (2 mg/kg daily for 24 months) for maintenance treatment in relapsing AAV patients after achievement of remission with RTX (ClinicalTrials.gov identifier: NCT01697267).

Despite the achievement of a better disease control with RTX, late disease flares still occur, mainly in patients with a history of relapse, in those with positive anti-PR3 at baseline or with a positive test for ANCA 12 months after RTX therapy (Specks et al, 2013).

Case series and uncontrolled studies have suggested that granulomatous manifestations respond less or slower to RTX. (Holle et al, 2012).

Most of the adverse events occurring during the therapy with RTX are infections. Few cases of *Pneumocystis jiroveci* pneumonia have been reported, so that a prophylaxis treatment with trimethoprim-sulfamethoxazole (400 mg/80 mg per day) is therefore advised until complete B repopulation (Charles et al, 2013). Moreover, a few cases of progressive multifocal leukoencephalopathy (PML) due to the JC virus have been also described (Molloy 2012, et al). Great caution is therefore needed when considering RTX therapy, in patients exposed to alkylating agents or having fewer than 200 CD4 cells/mm³. There is no evidence of an increased cancer risk with RTX (van Daalen et al, 2017). Cases of RTX induced neutropenia or vasculitis have been reported. Finally, RTX does not impair fertility in both male and female patients.

Anti-TNF alpha agents

TNF- α is associated with disease activity in AAV and its inhibition has been evaluated (Furuta et al, 2014). However, TNF inhibitors are not currently recommended in the treatment of AAV.

Infliximab has been used in refractory GPA, with no concomitant immunosuppressive treatment. Despite small open-label trials showing remission in infliximab-treated patients (Mukhtyar et al, 2005), a trend towards a lower efficacy of infliximab compared to RTX was observed in a long-term follow-up pilot study (de Menthon et al, 2011).

There is no place for etanercept in the management of patients with GPA or MPA. In the only available RCT, etanercept did not show any additional benefit to conventional therapy and was associated with a worse safety profile: six cancers were diagnosed during the trial, all in the etanercept arm (The Wegener's Granulomatosis Etanercept Trial Research Group, 2005).

Adalimumab has also been proposed as an adjunctive and glucocorticoid-sparing agent for the treatment of severe AAV, but further studies are required (Laurino et al, 2010).

Anti-T cells agents

The encouraging results observed with abatacept (CTLA4-Ig) treatment in a small open label study with non-severe relapsing GPA (Langford et al, 2014) await to be confirmed in an ongoing RCT (ABROGATE, ClinicalTrials.gov identifier: NCT02108860).

Alemtuzumab is an antibody targeting the CD52 antigen on lymphocytes. Its use in few patients with severe refractory vasculitides was associated with a good response, but relapse and adverse events were common (Walsh et al, 2008).

Other biologics

The role of tocilizumab, an IL-6 receptor antagonist, has been recently investigated in a small uncontrolled study, where it was administered in monotherapy with no glucocorticoids in MPA patients (Sakai et al, 2016). Complete remission was achieved in two of six patients at 6 months and three patients at 12 months. Larger studies are needed to better define its efficacy.

Belimumab, a human monoclonal antibody that inhibits B lymphocyte stimulator (BLyS), has been evaluated as maintenance treatment in ANCA-positive MPA and GPA (BREVAS, ClinicalTrials.gov identifier: NCT01663623).

EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS (EGPA)

In EGPA, most of the available literature relies on small uncontrolled studies due to the rarity of the disease.

Mepolizumab

The only published RCT has recently demonstrated the efficacy of mepolizumab (a monoclonal anti-IL-5 agent) compared with placebo in EGPA patients with relapsing or refractory disease over a 52-week follow-up period (Wechsler et al, 2017). Mepolizumab, administered subcutaneously every 4 weeks (300 mg dose), led to significantly more accrued weeks of remission than placebo (28% vs. 3%), a higher percentage of participants in remission at both week 36 and week 48 (32% vs. 3%), and allowed to receive a daily dose of prednisolone or prednisone of 4 mg or less per day in a significantly higher number of patients (44% vs 7%). The efficacy of mepolizumab in this trial was mainly due to a better control of asthmatic and ENT manifestations whereas its efficacy in vasculitis remains unclear. This biologic will help controlling the disease in those patients with recurrent and refractory asthma or ENT manifestations.

Rituximab

Pivotal RCT investigating RTX in AAV excluded EGPA patients because this disease is rarer and positive ANCA tests are less frequent than in GPA or MPA.

In the largest available series, 41 EGPA patients have been treated with RTX mostly for refractory or relapsing disease (Mohammad et al, 2016). Patients with positive ANCA testing were significantly more likely to achieve remission at 12 months (80% ANCA-positive vs 36% ANCA-negative). Apart infections, other safety issues included infusion reactions, among which some were severe (Mohammad et al, 2016; Bouldoyre et al, 2009). Very few patients have been described to have received RTX as maintenance therapy.

The French Vasculitis Study Group recommended that RTX can be prescribed to some EGPA patients with refractory disease responding only to high-dose glucocorticoids, particularly those with forms characterized by predominant inflammatory vascular disease (extracapillary glomerulonephritis, alveolar haemorrhage) and with positive anti-MPO ANCA (Charles et al, 2013).

Two RCT of the French Vasculitis Study Group aiming to determine the efficacy of RTX for inducing (REOVAS, ClinicalTrials.gov identifier: NCT02807103) or maintaining remission (MAINRITSEG, ClinicalTrials.gov identifier: NCT03164473) are ongoing in patients with EGPA.

Omalizumab

Omalizumab, an anti-IgE monoclonal antibody, is indicated in patients with convincing IgE mediated asthma. Small case series have suggested its usefulness for the control of refractory asthma and as steroid sparing agent in EGPA patients (Jachiet et al, 2016). However, further studies are needed before considering that omalizumab has no role in the onset of EGPA or in the vasculitis flares that have been observed during therapy.

CONCLUSION

The amount of evidence that biologics play a pivotal role in the treatment of AAV is rapidly increasing. RTX represents a good alternative to cyclophosphamide for inducing remission in patients with generalised GPA and severe MPA without increasing the risk of infertility and cancers. It has changed the standard of care for maintenance of remission in those patients. The best way to treat patients over time with this agent is object of ongoing studies and should probably be individually tailored according to the factors associated with relapse. Mepolizumab can be considered in EGPA patients with refractory asthma or ENT manifestations.

Behçet's disease, relapsing polychondritis, and eye symptoms in Rheumatic Diseases

David Saadoun, Cloé Comarmond, Nicole Stübiger

A previous version was coauthored by Hasan Yazici, Izzet Fresko, Nicole Stübiger

LEARNING OBJECTIVES

Part 1: Behçet's disease

- To recognise the signs and symptoms of Behçet's disease
- To describe the distinct geographical distribution of the syndrome, which is related to the ancient Silk Road, and its special place among the vasculitides
- To suggest a differential diagnosis, which is especially important for areas where the syndrome is rare
- To describe the natural course and prognosis of the various manifestations
- To evaluate treatment modalities, giving due consideration to evidence from the relatively few formal studies
- To plan an individual treatment strategy according to age, gender and the sites involved

Part 2: Relapsing polychondritis

- To recognise relapsing polychondritis (RP).
- To list and describe the diseases associated with RP.
- To recognise that RP may be a benign or a very severe disease.
- To manage different disease presentations.

Part 3: Eye involvement in rheumatic disease

- ➞ To describe, explain and investigate the various eye manifestations observed during the course of rheumatic diseases.
- ➞ To differentiate the prognoses of the different eye manifestations.
- ➞ To identify conditions where an ophthalmologic consultation is appropriate.

1 Behçet's disease

Although there has been global interest in Behçet's disease (BD) during the past two decades, the condition has been recognised since antiquity and was described by Hippocrates. The seminal paper by Hulusi Behçet, a professor of dermatovenereology at the University of Istanbul, was published in the 1930s. He followed up three patients for 17 years and defined the syndrome as the tri-symptom complex of oral aphthae, genital ulcerations and hypopyon uveitis. Later work showed that many other organ systems are also involved (Akman-Demir et al, 2011*).

There is debate about whether the entity described by Behçet is better designated as a disease or a syndrome (Direskeneli, 2006*). The authors prefer the latter given that we do not know the pathogenesis and there is no definitive diagnostic test.

1.1 Epidemiology

The pooled prevalence of BD is currently estimated at 10.3/100 000 inhabitants, as resulting from a global summary of data currently available in countries where epidemiological studies have been conducted on BD. However, BD has a distinct geographical distribution. Most cases come from countries around the Mediterranean basin and from Japan, while the syndrome is quite rare in Northern Europe, Northern Asia, most of continental Africa, Australia or the Americas. Specifically, pooled estimates of prevalence proportions expressed as cases/100 000 inhabitants is 119.8 for Turkey, 31.8 for the Middle East, 4.5 for Asia and 3.3 for Europe (Maldini, 2017*). Travel along the Silk Route has been implicated as the mechanism through which an etiological agent (eg, genetic or environmental) was spread.

Although it can affect every age group, onset before puberty or after the sixth decade is relatively rare. The usual onset is in the third decade. Sex distribution is roughly equal, but a male predominance has been described in some Middle Eastern and Mediterranean countries, while a female predominance has been reported in Japan and Korea.

A study carried out using the capture–recapture method among North African and Asian immigrants in Paris showed that: (a) the prevalence of BD was almost as high as that of other primary vasculitides (polyarteritis nodosa, Wegener's, etc) combined; (b) the prevalence was higher in immigrants than in the in-dwelling European population; and (c) BD risk was not related to age at immigration, suggesting a hereditary basis (Kirino et al, 2013a*). The prevalence of the disease was also low in the Armenian population of Istanbul, suggesting the role of genetic factors (Remmers et al, 2010*).

Some of the manifestations of BD also show regional differences. Gastrointestinal findings are common in Japanese patients (up to 58% of patients), but rather infrequent in Middle East and Turkey (1.4% to 3% of patients). The same is true for pathergy, the non-specific hypersensitivity of the skin to a needle prick, which is less commonly positive in European and US patients. Uveitis due to BD is also more common in countries where BD is more prevalent. A study has investigated potential ethnicity-related differences relative to phenotype and prognosis of patients with BD in a French multi-ethnic country (Savey et al, 2014*). They included 769 consecutive patients fulfilling the international criteria of classification for BD, in the three largest ethnic groups of our cohort (European (n = 369), North African (n = 350) and sub-Saharan African (n = 50)). Sub-Saharan African patients with BD had a higher frequency of central nervous system (CNS) involvement (48% vs 32.3% vs 29.5%, $p = 0.035$), a higher rate of death (12% vs 6% vs 3.5%, $p = 0.029$) and a lower frequency of the HLA-B51 allele (29.4% vs 49.2% vs 55.8%, $p = 0.009$) than those from North Africa and Europe, respectively. Multivariate analysis showed that male gender (HR = 5.01, 95% CI 1.51 to 16.65), cardiovascular involvement (HR = 2.24, 95% CI 1.15 to 4.36) and sub-Saharan African origin (HR = 2.62, 95% CI 0.98 to 6.97) were independently associated with mortality. The 15-year mortality rate was 19%, 9% and 6% in sub-Saharan African, North African and European patients with BD, respectively ($p = 0.015$).

1.2 Clinical spectrum

Skin and mucosa lesions, uveitis, major vessel disease and musculoskeletal, neurological and gastrointestinal manifestations are seen in varying combinations (Ideguchi et al, 2011*). The diagnosis is clinical and a course characterised by remissions and exacerbations is typical. The intensity of the attacks decreases with the passage of time.

BD is usually described as a systemic vasculitis that affects many organs. However, in many instances (eg, parenchymal CNS disease) a true vasculitis cannot be demonstrated. Thus, a better designation would be to describe the condition as a 'systemic inflammation'. In this regard, BD has recently been included among polygenic and multifactorial autoinflammatory diseases also on the basis of clinical presentation, that resembles the clinical framework of monogenic autoinflammatory disorders (Vitale et al, 2016a*).

Table 1 shows the frequency of the main clinical manifestations.

Table 1 Frequency of clinical manifestations of Behçet's disease

Manifestation	Frequency (%)
Oral ulcers	97–99
Genital ulcers	85
Genital scar	50 (probably more prevalent in men)
Skin lesions	
Papulopustular lesions	85
Erythema nodosum	50
Pathergy reaction	60 (Mediterranean countries and Japan)
Uveitis	50
Arthritis	30–50
Subcutaneous thrombophlebitis	25
Deep vein thrombosis	15
Arterial occlusion/aneurysm	5–10
Central nervous system involvement	20
Epididymitis	5
Gastrointestinal lesions	1–58 (more prevalent in Japan)

1.3 Mucocutaneous manifestations

1.3.1 Oral ulcers

Oral ulcers are seen in 97-99% of patients and are often the first disease manifestation (figure 1). They resemble ordinary aphthae but are more frequent and multiple. They often appear as erythematous, circular and slightly raised areas evolving into oval or round ulcers within 48 h.

Figure 1 Oral ulcers in Behçet's disease.

They have traditionally been defined as minor, major and herpetiform according to their size and location; >90% are of the minor type. They are <10 mm in diameter and are often seen on the mucous membranes of the lips, gingiva, cheeks and tongue, perhaps more posterior than ordinary aphthae, and are seen in 15% of the normal population. They usually heal in about 15 days without scarring. Tobacco use decreases their frequency and severity, whereas stopping smoking seems to exacerbate them.

Less frequently, oral ulcers can present as major aphthae, which are larger than 10 mm and usually require a longer healing process (weeks or months) often resulting in scarring. Finally, herpetiform aphthae are smaller (1-3 mm), grouped or coalescent and heal over 1 to 4 weeks.

1.3.2 Genital ulcers

Genital ulcers are usually located on the scrotum in men and on the major and minor labiae in women. Less common locations are the shaft and glans penis and the vaginal and cervical areas. The inguinal area, pubis and perineum are occasionally affected in both sexes. They usually begin as papules or pustules that ulcerate after a short time (figure 2). Compared with oral ulcers, they are larger, deeper, less recurrent and more resistant to healing. They usually heal in 10–30 days if they are not secondarily infected, and leave scars in about 60% of patients. Scar formation is more common if the diameter of the ulcer is >1 cm. Genital scarring is usually good evidence of BD in a patient suspected of having this syndrome.

Figure 2 Genital ulcers in Behçet's disease.

1.3.3 Other skin lesions

The other types of skin lesions can be divided into three broad categories: (a) erythema nodosum-like lesions and superficial thrombophlebitis; (b) papulopustular lesions and (c) other lesions such as skin ulcers and Sweet's syndrome. Erythema nodosum-like lesions are seen in 50% of patients and morphologically resemble the idiopathic or secondary variants (figure 3). Histopathology shows more evidence of vasculitis in lesions associated with BD than in lesions due to other causes.

The superficial thrombophlebitis looks like erythema nodosum. It is more common in men and is characterised by a thrombosed vein on biopsy. Ultrasonography may differentiate the two lesions.

Figure 3 Erythema nodosum-like lesion in Behçet's disease.

The papulopustular lesions resemble ordinary acne (figure 4). They are seen at the usual acne sites such as the face, upper chest and back, and additionally on the legs and arms. They are usually colonised by *Staphylococcus aureus* and *Prevotella* species and are more common in a subgroup of patient with arthritis. Skin ulcers and Sweet's syndrome may occasionally be seen.

Figure 4 *Ostiofolliculitis in Behçet's disease.*

1.4 Pathergy

The pathergy phenomenon is a non-specific hyper-reactivity in response to minor trauma. Although it has a moderate sensitivity ($\approx 50\%$), it is highly specific for BD ($>95\%$). It is usually used as a diagnostic test and is performed by inserting a 20 gauge needle into the dermis of the forearm of the patient. The test is positive when the development of a papule or pustule is observed at the needle-prick site after 24–48 h (figure 5). The rate of positivity is not related to the severity or the site of involvement, although male patients tend to have stronger reactions. It also has a limited reproducibility and may vary in intensity in the same patient if performed repeatedly. It is a useful test in Mediterranean, Near Eastern and Far Eastern countries, although it may be less so in continental Europe or the Americas. Interestingly, increasing evidences suggest a decline in the positive rate of skin pathergy test over the past four-five decades worldwide. This could be related to racial differences as well as different methodology used to perform the pathergy test, including the use of disposable needles instead of blunt, reusable, sterilized needles.

Figure 5 Positive pathergy reaction.

1.5 Eye involvement

Eye involvement in BD causes serious morbidity and is a common cause of blindness in the Mediterranean basin, Middle East and Far East. It is found in 50% of patients, but the frequency reaches 70% in young men aged <25 years. It is usually seen during the first 2 years of the syndrome and is bilateral in 70–80% of patients. The most frequent pattern is a non-granulomatous panuveitis not infrequently accompanied by a retinal vasculitis. Hypopyon formation (figure 6), which is a collection of pus in the anterior segment, is seen in about 20% of patients with eye involvement and is nearly always accompanied by additional posterior inflammation. Isolated anterior involvement is uncommon and conjunctivitis, corneal ulcerations and scleritis are rare occurrences. Recurrent bouts of inflammation lead to structural damage characterised by posterior synechiae, complicated cataracts, optic atrophy and macular degeneration. Total loss of vision is seen in 20% of cases with uveitis, even after treatment.

Ophthalmological consultation with indirect ophthalmoscopic and slit lamp examination must be performed for every patient with vision problems, since correct diagnosis and the prevention of ocular attacks are the most effective means of avoiding blindness.

Figure 6 Hypopyon uveitis in a patient with Behçet's disease. Patient consent obtained.

1.6 Central nervous system disease

Neurological involvement is seen in 5% of patients with BD. It usually occurs after the first 5 years of disease and almost never as a presenting feature. Two main patterns of involvement are seen: vascular and parenchymal. Parenchymal disease leads to inflammatory lesions in the brain stem, diencephalon, basal ganglia and, less frequently, the spinal cord and cerebellum. The cerebral cortices seem to be spared. It usually manifests as bilateral pyramidal signs, unilateral hemiparesis, behavioural changes, sphincter disturbances and headache. Brainstem signs and sensory disturbances are less common. Abnormal cerebrospinal fluid findings, such as pleocytosis and increased cellularity, are found in 60% of patients with parenchymal involvement. Magnetic resonance imaging (MRI) is more sensitive than CT for imaging and the characteristic lesion is a pathological signal with contrast enhancement in the brainstem and basal ganglia regions (figure 7).

Figure 7 Magnetic resonance image of parenchymal central nervous system involvement in a patient with Behçet's disease.

A recent study has claimed that susceptibility-weighted imaging—an MRI modality sensitive to microhaemorrhages and venous flow—performs better than standard sequences in detecting parenchymal neurological disease.

Frequent attacks, a progressive course and abnormal cerebrospinal fluid findings indicate a bad prognosis. About 25% of patients in this category will have some disability in 10 years' time.

The second pattern of neurological involvement is dural sinus thrombosis (figure 8), mainly characterised by headache and papilloedema. It is usually associated with deep vein thrombi in other areas and has a better prognosis than parenchymal involvement.

Sensorineural hearing loss has recently been found to be a common underrated feature of BD, especially in patients with cutaneous plus articular involvement, but there are no studies evaluating the histological basis of inner otologic involvement (Sota et al, 2016*).

Figure 8 Magnetic resonance image of a dural sinus thrombosis in a patient with Behçet's disease.

The presence of headache in a patient should not be ascribed to neurological involvement unless it is associated with neurological symptoms, since tension type headaches are common in patients with BD.

Cognitive impairment in the form of 'frontal' executive dysfunction is also common.

1.7 Major vessel involvement

BD can affect both venous and arterial vessels, the former being more common than the latter. Venous thrombosis is seen in about 20% of patients with BD, throughout the disease course. According to studies on Turkish patients, major vessel involvement is more frequently seen in men and overall is found in up to 40–50% of patients; 60–80% of these lesions are venous thromboses of the deep veins of the lower extremities. Conversely, large-vessel involvement is less frequent in Japan.

The involvement of inferior and superior vena cavae, dural sinuses and axillary, brachial, hepatic and portal veins is a less frequently described event (Espinosa et al, 2002*).

Chronic recurrent thrombosis of the lower extremities leads to erythema, dermatitis, hyperpigmentation and, subsequently, crural ulcers (figure 9). Many patients with chronic venous insufficiency report claudication-like lower extremity pain on walking despite the absence of arterial obstruction (i.e., venous claudication). Chronic obliteration of the caval system leads to venous collaterals on the thoracic and abdominal walls. Obstruction of the superior vena cava may also cause oesophageal varices, chylothorax and chylous pericardial effusions.

Figure 9 Chronic thrombosis and a skin ulcer in a patient with Behçet's disease with longstanding deep vein thrombosis.

Budd–Chiari syndrome resulting from hepatic vein occlusion presents with ascites and liver failure. It is a rare complication of BD, but carries a high death rate. One should be aware that venous thrombi may precede and be an impending sign of arterial inflammation in BD.

Systemic artery involvement may be seen in 1.5–7.5% of patients. The typical lesions are aneurysmal, or uncommonly, occlusive. The abdominal aorta is the most frequently affected site followed by the iliac, femoral, popliteal, carotid and subclavian vessels. Renal, cerebral or coronary arteritis and abdominal visceral ischaemia are uncommon.

Peripheral arterial involvement may translate into reduced or absent pulses with intermittent claudication, cold extremities or even gangrene. Abdominal aortic aneurysms sometimes produce abdominal pain. Bruits can be heard over the affected large arteries and a pulsating mass may be found. Most patients with arterial lesions have constitutional signs and symptoms, such as fever and weight loss.

Pulmonary arterial aneurysms are the most devastating arterial involvement in BD (Hamuryudan et al, 2004*). They are usually seen in the young male patient, who often has thrombosis of the leg veins or the vena cavae, and are manifested by recurrent haemoptysis, dyspnoea and pleuritic chest pain. Pulmonary aneurysms had a death rate of 50% in the 1980s but this figure has decreased to 20% in recent years owing to earlier recognition and better use of immunosuppressive drugs.

These lesions are usually suggested by parahilar or perihilar non-cavitating opacities found on chest X-ray examination (figure 10) and CT scan, and pulmonary angiograms show single or multiple aneurysms in the

pulmonary arteries. Isolated thrombosis of the peripheral segments of pulmonary arteries with or without aneurysms can also be seen. Mediastinal lymphadenopathy, nodules, cavities and consolidations are also seen and are often confused with secondary infections in an immunocompromised patient.

Figure 10 *Chest radiograph of a patient with Behçet's disease with bilateral pulmonary artery aneurysms.*

One should be aware that, in such cases, the ventilation–perfusion scan may mimic pulmonary embolism. The thrombi in BD do not embolise, presumably owing to their sticky nature and their tight adherence to inflamed veins.

1.8 Musculoskeletal manifestations

Arthritis or arthralgia is seen in about 50% of patients during the course of the disease. It may precede the other findings by months or years and usually manifests as an oligoarthritis involving, in decreasing order, the knees, ankles, hands and wrists. It is usually a self-limiting synovitis with an acute onset and resolves in a couple of days to weeks. Deformities are not usual, although they may rarely occur. Synovial fluid examination shows a mild inflammation dominated by polymorphonuclear leucocytes, but the mucin clot is normal.

Sacroiliitis is not a prominent part of the clinical picture, but the coexistence of acne, arthritis and enthesopathies suggests that at least a subgroup of patients may present with spondyloarthritis-like features. However, the co-existence of BD and ankylosing spondyloarthritis is to date yet relegated to an increasing number of case reports, not sufficient to draw firm conclusions on a possible association between the two clinical entities.

Fibromyalgia and local inflammatory myositis confined to the leg are possibly seen. According to a recent study conducted on 30 Egyptian patients, the frequency of fibromyalgia was 3.33 (El-Rabbat et al, 2017*), but previous studies had identified higher frequencies ranging from 9.2% to 18% in Turkish studies (Melikoglu et al, 2013*) and to 37.1% in a Korean study (Lee et al, 2005*).

1.9 Gastrointestinal involvement

Gastrointestinal involvement is seen in 6% of patients, being a frequent finding in the Far East, whereas it is usually not a prominent manifestation in patients from the Middle East. Patients usually present with mild symptoms including abdominal pain, diarrhoea, nausea or vomiting. Conversely, gastrointestinal bleeding and inflammatory bowel disease-like symptoms are more rare. Mucosal ulcerations resemble those found in inflammatory bowel diseases with normal intervening mucosa. Three-quarters of the ulcerations are found in the terminal ileum and the caecum, with the remainder being found in the oesophagus, stomach and duodenum. Rectal involvement is rare. Patients complain of vomiting, abdominal pain and diarrhoea. A mass is often palpable in the abdomen during exacerbations, and ileocaecal perforations may occur.

It is sometimes difficult to distinguish the findings of gastrointestinal BD from those of Crohn's disease. The presence of oral and genital ulcerations, with round, focal and isolated intestinal ulcers on endoscopy and frequent perforations favour the former, whereas perianal disease, fistula and stricture formation, the occasional presence of a granuloma in histopathology and longitudinal, diffuse and segmental ulcerations in endoscopy favour the latter.

The occasional patient with isolated findings of bowel inflammation and the absence of other manifestations of BD should be followed up meticulously since the diagnostic criteria are usually fulfilled after considerable follow-up. Younger age at diagnosis is associated with a more severe clinical course and a poorer prognosis.

A disease activity index for gastrointestinal BD has been developed with the aim to differentiate quiescent, mild, moderate and severe disease (Cheon et al, 2011*). Table 2 shows this index.

Table 2 shows the disease activity index for patients with gastrointestinal BD proposed by Cheon et al (Cheon et al, 2011). The table has been drawn by Cheon et al, 2011. The gastrointestinal is severe for scores ≥ 75 , moderate for scores ranging between 40 and 74, mild for scores between 20 and 39, quiescent for scores ≤ 19 . Symbols : * Score 5 for oral ulcer, genital ulcer, eye lesion, skin lesion, or arthralgia; score 15 for vascular involvement or central nervous system involvement. † Fistula, perforation, abscess, or intestinal obstruction.*

1.10 Urological problems

The three problems related to the genitourinary system in BD are epididymitis, cystitis and erectile dysfunction. Epididymitis is seen in up to 20% of male patients and manifests as testicular pain. A patient with BD may have neurogenic bladder with or without demonstrable involvement of the spinal cord. Erectile dysfunction occurs in two-thirds of patients with neurological involvement. The frequency of varicocele is also increased among patients with BD.

1.11 Other manifestations

The heart is rarely affected during the course of BD, although various conduction abnormalities and valvular problems are occasionally seen. One peculiar manifestation is right-sided endomyocardial fibrosis with intracardiac thrombi—a finding seen in men with widespread vascular disease.

Glomerulonephritis is occasionally seen, with pathology ranging from immunoglobulin A (IgA) nephropathy to rapidly progressive inflammation. Immune complexes are not commonly found.

Secondary amyloidosis of the AA type has been reported in 0.04–3% of patients. It is predominantly seen in men, is closely associated with large vessel disease and arthritis, and has a death rate of >50% within 3.5 years after onset.

1.12 Histopathology

No specific cell type dominates in vasculitic lesions. In fact, neutrophils and mononuclear cells with high predominance of T lymphocytes (mostly CD4⁺ cells), and few B lymphocytes, NK and macrophages cells can be observed at immunohistochemical analysis of vascular infiltrates in BD inflammatory lesions. Predominance of cytotoxic CD8⁺CD56⁺NKT cells and of CD8⁺CD56⁻ T cell have been described in the eye involved by inflammatory BD lesions.

The histology of oral aphthae is similar to the aphthae present in recurrent oral stomatitis. Arterial and venous vessels of all sizes may be affected in BD with a peri- and intra-vascular inflammatory infiltrate eventually provoking stenosis, blood clots, and aneurysms. Direct injury to the vessel wall can sometimes be seen, such as in oral and genital ulcers, erythema nodosum-like lesions and local myositis. In erythema nodosum lesions histology generally show characteristics of septal panniculitis with infiltration of neutrophils. However, lobular panniculitis with vasculitis can also be seen in some cases, while granuloma formation is rarely seen.

Vascular injury is also found in uveitis and major vascular disease such as arterial aneurysms or major vein occlusions. On the other hand, for some lesions direct evidence of injury to the vascular wall cannot be shown. Among these are the acne lesions of the skin, where histology is no different than for ordinary acne, and in parenchymal lesions of the brain, where direct vessel wall injury is difficult to demonstrate.

Histology of the synovial membrane shows features of nonspecific synovitis

1.13 Pathogenesis

The pathogenesis of BD remains unclear. The relative risk of having BD in the siblings of affected individuals has been estimated to be between 11 and 53, implying a genetic influence on disease development. Although an autosomal recessive inheritance pattern has been suggested among paediatric patients, Mendelian inheritance patterns seem not to be operative. Genetic anticipation in the form of earlier disease onset in the second generation compared with their affected parents has also been reported. HLA-B51 has been the most consistently reported HLA association, and has been shown in many ethnic groups, although with differing risk ratios, and has lately been confirmed in a whole genome analysis in 2430 cases and 2660 controls along with interleukin (IL)-10 and IL23R-IL12RB2 loci (Mizuki et al, 2010*). Imputation analyses of genome-wide association studies showed new associations such as ERAP-1, CCR1-CCR3, KLRC4 and STAT4. The absence of concordance in monozygotic twins, however, suggests that other factors are also involved in pathogenesis.

BD does not exhibit the properties of a true autoimmune disease: it lacks consistent autoantibodies, there is no secondary Sjögren's syndrome and the prevalence of autoimmunity is not increased. Nor is it a typical autoinflammatory disease. However, a targeted resequencing study among patients with BD found variants of IL-23R, IL1R1 and NOD2 among the Japanese and IL-23R, TLR4, MEVF (M694V) and NOD2 among the Turks, suggesting that certain autoinflammatory aspects may be operative (Kirino et al, 2013b*). Consequently, the latest approach to BD pathogenesis supports the idea that both the innate and adaptive immune systems have a role in the induction of the disease. Actually, numerous pathogenetic evidences support the autoinflammatory hypothesis, especially about role of the primed state of neutrophils IL-1 that has been found significantly higher in patients with both active and inactive BD compared to healthy controls (Keller et al, 2005*). In addition, IL-1 production by monocytes stimulated with lipopolysaccharide is even higher in BD patients compared to subjects with familial Mediterranean fever (FMF), the prototype of IL-1 related autoinflammatory disease (Mege et al, 1993*). Also, single nuclear polymorphisms of IL-1 gene have shown to be significantly more represented in BD patients than healthy (Liang et al, 2013*). In support of these findings, IL-1 inhibition has revealed to be a good therapeutic option for BD patients.

Interestingly, toll-like receptors (TLRs)-2, -4 and -9, which are involved in both innate and acquired immunity, are implied in the pathogenesis of BD. In particular, TLR-2 and TLR-4 up-regulate IL-1 β production in active BD patients through a ROS-NLRP3 inflammasome pathway, while TLR-9, whose polymorphisms are significantly more frequent in BD patients, is involved in different autoimmune and autoinflammatory disorders (Sakamoto et al, 2012*). The higher expression of the P2X7 receptor (P2X7r) in monocytes from BD patients also supports the autoinflammatory nature of the disease. The P2X7r is an ion channel promoting the release of

proinflammatory cytokines, especially IL-1 β , by means of a massive potassium efflux that in turn allows the assembling of the NLRP3 inflammasome (Castrichini et al, 2014*).

On the other side, BD shares with autoimmune diseases the association with a class I major histocompatibility complex (MHC) and is successfully treated with disease modifying anti-rheumatic drugs (DMARDs). In addition, the therapeutic benefit observed with interferon- α supports the hypothesis of a Th1-driven disease.

In any case, what drives the immune system and sustains the inflammation is not clear, but an infectious trigger linked to an innate immune abnormality (eg, a genetic mutation affecting an adhesion molecule, a proinflammatory cytokine or an intracellular signalling abnormality of a transcription factor) is an attractive hypothesis. The diminished mRNA expression and low protein production of the disease-associated IL-10 variant (the rs158111 A allele) in the whole-genome study mentioned above support this hypothesis since IL-10 production usually has an inhibitory role in inflammation. The inhibitory properties of IL-10 in eye disease have also been shown.

There is evidence that the clinical picture is not homogeneous and that there are various clusters of disease expression. A factor analysis has shown that superficial vein thrombosis, deep vein thrombosis, and dural sinus thrombi represent a disease cluster on one hand, while acne, arthritis, and enthesitis are another cluster on the other. Notably, acne and arthritis also cluster in families. The presence of such clusters may additionally suggest that different mechanisms are operating in the pathogenesis of the various subgroups of patients.

The aetiology of the thrombophlebitis deserves a special mention. Indeed, it has been the subject of controversy, as some claim that it is the result of procoagulant factors, whereas others suggest that it is caused by endothelial inflammation. To date, although increased levels of homocysteine have been observed in BD patients, none of the procoagulant factors are definitely associated with the thrombotic tendency of BD and no significant differences have been found in terms of coagulation parameters between patients with and without thrombosis. However, a procoagulant state has been observed in BD patients compared to healthy controls even when thrombosis is absent. This finding seems to be related to increased levels of fibrinogen and plasminogen activator inhibitor(PAI)-1 along with an increased generation of thrombin after unspecific stimuli (Fernández-Bello et al, 2013*). Overall, the procoagulant and antifibrinolytic state of BD seem to be related to endothelial activation/damage, which in turn may be owing to the increased oxidative condition associated with systemic inflammation.

1.14 Diagnosis and laboratory findings

The diagnosis of BD is clinical. A group of doctors involved in the care of large numbers of patients with BD formed the International Study Group (ISG) and in 1990 published the ISG criteria for diagnosis (table 3). Oral ulceration was the essential factor, as its presence was almost universal. However, one must be aware of the

fact that the utility of the criteria is dependent on the prevalence of the syndrome in the background population. There may also be atypical patients who do not fulfil the criteria. New international criteria for BD (ICBD) were published in 2014 taking into account vascular and neurological involvement (table 4). ICBD are based on a scoring system attributing 1 or 2 points to seven different BD signs/symptoms. Two points are attributed to oral aphthosis, genital aphthosis and ocular lesions, which represent the basilar triad of BD; the other signs and symptoms have a weight of 1 point. A scoring ≥ 4 classifies patients as having BD. Comparing the performance of the two set of criteria, ISG criteria have sensitivity and specificity of 85% and 96%, respectively; ICBD exhibit a sensitivity of 94.8% and a specificity of 90.5%.

Important considerations in the differential diagnosis are summarised in table 5.

Table 3 International Study Group criteria for the diagnosis of Behçet's disease. (Reproduced with permission from International Study Group for Behçet's disease, Lancet 1990;335:1078–80)

Manifestation	Definition
Recurrent oral ulceration	Minor aphthous, major aphthous or herpetiform ulcers, observed by a physician or reported reliably by patient, recurring at least three times in one 12-month period
Plus any two of the following findings:	
Recurrent genital ulceration	Recurrent genital aphthous ulceration or scarring, observed by a physician or reported reliably by patient
Eye lesions	Anterior uveitis, posterior uveitis, or cells in vitreous on slit lamp examination; or retinal vasculitis observed by qualified physician (ophthalmologist)
Skin lesions	Erythema nodosum-like lesions, observed by a physician or reported reliably by patient, pseudofolliculitis or papulopustular lesions; or acneiform nodules observed by a physician in post adolescent patients not receiving glucocorticoids
Positive pathergy test	Test interpreted as positive by a physician at 24–48 h, performed with oblique insertion of a 20 gauge or smaller needle under sterile conditions

Table 4 International Criteria for Behçet's disease. This set of criteria is based on a score system. Patients are classified as having BD for scores ≥ 4 . †Pathergy test is optional: in Countries where the test is performed, adding 1 point for pathergy test increases sensitivity from 95.5% to 98.5%, while specificity decreases from 92.1% to 91.6%.

BD manifestations	Score assigned
Ocular lesions	2
Oral aphthosis	2
Genital aphthosis	2
Skin lesions	1
Neurological manifestations	1
Vascular manifestations	1
Positive pathergy test†	1

Laboratory investigation is of little help in the diagnosis of BD, as no specific laboratory abnormality supports or excludes the diagnosis. A mild anaemia of chronic disease and neutrophilic leucocytosis are seen in 15% of patients, but they do not correlate with the clinical activity of the disease. The erythrocyte sedimentation rate and C-reactive protein may be moderately raised, especially with episodes of arthritis, erythema nodosum and acute thrombophlebitis. Young male patients with unexplained sustained acute phase response should be investigated for large vessel disease in the thorax or abdomen. The role of serum amyloid-A (SAA) has also been investigated in recent times. Higher levels of SAA could anticipate the occurrence of BD manifestations. A recent study found that SAA serum levels higher than 30, 50, and 150 mg/L were significantly associated with the occurrence of oral aphthosis, neurological impairment, and ocular disease, respectively. In addition, increased SAA levels might represent a mirror of thrombotic risk in patients with previous or concurrent vascular involvement (Vitale et al, 2014a*).

Rheumatoid factors and antinuclear antibodies are absent and tests for antineutrophil cytoplasmic antibodies are usually negative. Patients with BD who have gastrointestinal involvement seem to have high levels of anti-Saccharomyces cerevisiae antibodies, although larger numbers of patients are needed to confirm this. A soluble triggering receptor expressed on myeloid cells (sTREM-1) and anti- α -enolase antibody titres seem to correlate with clinical disease activity in gastrointestinal BD. Levels of IL-33 have showed to be significantly increased in BD patients with cutaneous and retinal vasculitis ; in addition, IL-33 exhibited a positive correlation with disease activity evaluated with BD Current activity Form (BDCAF) and was found between BDCAF score and IL-33 serum levels. However, the clinical usefulness of these tests is unknown. Low-titre anticardiolipin antibodies may occasionally be found in patients with thrombosis but are not of major concern.

HLA-B51 testing may be of help in patients who exhibit features of BD that cannot be explained otherwise and do not fulfil the ISG criteria. These are generally patients with uveitis or young men with an arterial aneurysm or venous thrombosis who do not have oral ulcers. The presence of HLA-B5/B51 has a constant effect on the disease among various ethnicities and the positivity ranges around 40–60% (Kirino et al, 2013a*). However, diagnoses other than BD should be considered in a suspected 'incomplete' BD case in a low-prevalence region before resorting to HLA testing.

Table 5 Highlights of the clinical manifestations of Behçet's disease and differential diagnosis

Area affected	Clinical features
Mouth ulcers	Majority similar to common aphthous ulcers in appearance, localisation and discomfort/pain; more frequent and often multiple; may scar
Genital ulcers	Most commonly scrotal or vulval, painful, recurrent and usually with scarring; urethral discharge and penile lesions very rare
Skin	Acneiform lesions similar to common acne in appearance and histology but also at uncommon sites such as the extremities; erythema nodosum-like lesions leaving pigmentation; not psoriasis
Eyes	Panuveitis and retinal vasculitis, usually bilateral, occurring within about 2 years of disease onset; conjunctivitis and sicca syndrome most unusual
Joints	Monoarthritis in 50%, otherwise oligoarticular or polyarticular involving relatively few joints; may be symmetrical; knees most often affected; intermittent and resolving in 2–4 weeks or chronic and continuous; not involving sacroiliac joints or spine; deformity and erosions rare, synovial fluid usually inflammatory with good mucin clot
Peripheral arterial and venous disease	Subclinical peripheral large vein disease uncommon, usually involves large segments with skip areas without embolisation; arteritis with pseudoaneurysms or less commonly occlusions; microaneurysms of the polyarteritic type very uncommon
Neurological involvement	Acute brainstem syndrome with pyramidal and cranial nerve signs; typical MRI of the brain shows contrast enhancing lesion extending from basal ganglia to brainstem; less commonly, myelitis with paraplegia and bladder dysfunction and sensory loss distal to cord lesion; convulsions, MS-like disease, optic neuritis and peripheral neuropathy uncommon
Pulmonary involvement	Haemoptysis associated with pulmonary arterial aneurysm; pulmonary artery occlusion; pleural involvement uncommon; interstitial involvement not expected
GI involvement	Severe abdominal pain; ulcerative lesions at any level but mainly in the ileocaecal region; mild GI symptoms should not be associated with BD
Cardiac disease	Pericarditis, valve lesions and coronary artery involvement uncommon; rarely intracardiac thrombi

BD, Behçet's disease; GI, gastrointestinal; MRI, magnetic resonance imaging; MS, multiple sclerosis.

1.15 Management

Therapeutic management of BD depends on the severity, clinical presentation and organs involved. Although colchicine, non-steroidal anti-inflammatory drugs (NSAIDs) and topical treatments with glucocorticoids are often sufficient for mucocutaneous and joint involvement, a more aggressive approach with immunosuppressive agents is warranted for severe manifestations such as posterior uveitis, retinal vasculitis, vascular, neurological and gastrointestinal involvement (Yazici et al, 2007*). After this, some patients will still have refractory disease, relapses, sight-threatening eye disease or irreversible organ damage. Recent improvements in understanding the pathogenic mechanisms have led to the identification of potential targets and future treatments for BD (Arida et al, 2011*; Comarmond et al, 2014*). In this context, biological treatments with tumour necrosis

factor(TNF) α inhibitors have proved to be a substantial role in the treatment of resistant cases or life- and/or sight-threatening conditions (Calvo-Río et al, 2014*; Vallet et al, 2015*; Vitale et al, 2017a*; Fabiani et al, 2017a*). Also IL-1 inhibitors may be taken into account in cases resistant to TNF α inhibition, as well as anti-IL-6 agents and interferon α (Fabiani et al 2017b*; Cantarini et al. 2015*; Emmi et al, 2016*). However, novel treatment options are emerging as possible therapies in patients with specific BD manifestations (Cantarini et al, 2016*; Vitale et al, 2016a*). In contrast to current non-specific immunosuppressive agents, the emergence of immunomodulatory drugs provides the possibility of interfering with specific pathogenic pathways. New targeted immunosuppressive therapies might be used in the future for BD.

Management of the systemic manifestations is summarised below.

1.15.1 Mucocutaneous manifestations

Studies aimed at assessing the treatment of BD oral aphthosis are currently lacking, as current management is based on evidences drawn from studies performed on recurrent aphthous stomatitis.

Initially, treatment of oral and genital aphthosis is topical with antimicrobial agents, sucralfate, topical glucocorticoids, amlexanox and lidocaine gel; however, in resistant and disabling cases systemic options should be taken into account. Wet dressings with aluminium acetate 3–5% may represent a useful topical treatment for erythema nodosum.

Although there is no solid evidence to show that it is beneficial for all mucocutaneous lesions, colchicine, combined or not with short-term systemic corticosteroids, has been widely used for oral and genital ulcers and for skin manifestations.

Azathioprine (AZA) or thalidomide has also been reported to be efficacious for treating patients with mucocutaneous lesions refractory to treatment with colchicine. However, teratogenicity, neurotoxicity and constipation restrict usage of thalidomide. In addition, erythema nodosum lesions may worsen during thalidomide treatment.

Pentoxifylline, which reduces the production of proinflammatory cytokines such as TNF, was effective in reducing the frequency and severity of oral and vaginal ulcers. In an open trial, dapsone was shown to improve severe skin lesions. TNF α blockers have increasingly been used in the treatment of BD. Almost all trials with anti-TNF α agents reported encouraging results for recalcitrant mucocutaneous lesions. A controlled, 4-week trial with etanercept among male patients showed that it was effective in controlling most of the mucocutaneous manifestations of BD but did not suppress the pathergy phenomenon. Among agents inhibiting other cytokines, based on case series the anti-IL-1 β canakinumab has induced a prompt and sustained clinical efficacy in oral and genital ulcers (Vitale et al, 2014b*). Conversely, in 9 patients treated with the IL-1 receptor antagonist anakinra mucocutaneous lesions appeared the most refractory despite the global response (Cantarini et al, 2015*). A

pilot open-label two-phase clinical trial conducted on 6 BD subjects with ongoing oral/genital ulcers found that two out of six patients reached remission defined as the absence of ulcers at two consecutive monthly visits performed between 3 and 6 months after the start of anakinra at the dose of 100 mg/day. Contrariwise, an improvement in the number and severity of ulcers was seen in 5/6 patients. Nevertheless, oral and genital ulcers were reported on 66% and 14% of the entire study time (16 months), respectively. Increasing the dosage to 200 mg/day significantly reduced the number of days with oral or genital aphthosis and allowed a milder severity of oral ulcers. Conversely, increasing anakinra to 300 mg/day did not result in further improvements (Grayson et al, 2017*).

The anti-CD20 monoclonal antibody rituximab has also demonstrated to be effective on mucocutaneous lesions, but current evidences are based on a single case report (Zhao et al, 2014*). On the contrary, the inhibition of IL-6 is not desirable in BD patients with predominant mucosal and skin involvement, as tocilizumab has proved a worsening of skin manifestations (Diamantopoulos et al, 2013*).

In a phase 2, multicentre, placebo-controlled study in which 111 patients with Behçet's syndrome who had two or more oral ulcers were randomly assigned to receive 30 mg of Apremilast twice daily or placebo for 12 weeks, the mean (\pm SD) number of oral ulcers per patient at week 12 was significantly lower in the Apremilast group than in the placebo group (0.5 ± 1.0 vs. 2.1 ± 2.6) ($P < 0.001$). The mean decline in pain from oral ulcers from baseline to week 12 was greater with Apremilast than with placebo (-44.7 ± 24.3 mm vs. -16.0 ± 32.5 mm) ($P < 0.001$) (Hatemi et al, 2015*).

1.15.2 Joint involvement

In two double-blind trials, colchicine was efficient in controlling arthralgias and reducing the occurrence of arthritis. For refractory exacerbations, agents such as NSAIDs, methotrexate, AZA or, in the most refractory cases, anti-TNF α , should be tried.

1.15.3 Ocular involvement

Uveitis and retinal vasculitis are sight-threatening manifestations of BD, with limited treatment options. Despite early treatment with glucocorticoids and immunosuppressant agents, up to 20% of patients become blind. Any patient with BD and inflammatory eye disease affecting the posterior segment should be following a treatment regimen including AZA and systemic glucocorticoids. If the patient has severe eye disease, defined as loss of visual acuity (>2 lines in the Snellen Eye Chart—a test to measure a person's distance visual acuity) and/or retinal disease (retinal vasculitis or macular involvement), it is recommended that either cyclosporine A (CsA) or infliximab (IFX) be used in combination with AZA and glucocorticoids.

According to an expert panel for the use of anti-TNF biologic agents in patients with ocular disorders (Levy-Clarke et al, 2014*) the use of IFX and adalimumab (ADA) is recommended as first-line therapy for the treatment of

ocular BD manifestations. Regarding IFX, an open-label study on 50 patients with refractory posterior uveitis (36 of which diagnosed with BD) pointed out a complete response in 68% of patients and a partial response in 22% after IFX treatment at the end of a mean follow-up of 36.8 months. Moreover, a significant improvement was observed in the mean visual acuity and a significant reduction of both ocular attacks and patients with cystoid macular oedema were observed, with no differences between subjects with BD and those with idiopathic posterior uveitis (Cantini et al, 2012*). Similarly, a study on 48 Japanese patients found an improvement of uveoretinitis in 44 after 1 year of IFX therapy (Okada et al, 2012*) and a study on 124 patients with refractory BD-associated uveitis showed that treatment with IFX or ADA had allowed remission of uveitis in 67.7% of cases at 1 year follow-up (Calvo-Río et al, 2014*). In this regard, Vallet et al (Vallet et al, 2015*) even reported a response to IFX or ADA in 96.3% of 80 patients with severe and refractory BD-related uveitis (Vallet et al, 2016*). A literature review on the use of anti-TNF α agents in 369 BD patients showed a sustained response in 89% of patients with uveitis treated with IFX and in all the few patients treated with ADA (Arida et al, 2011*). In a recent multicentre observational study on 160 patients with uveitis that had been refractory to other therapies, including 36% of BD, the overall response rate at 6 and 12 months was 87% (26% with complete response) and 93% (28% with complete response), respectively. The median time to complete response was 2 months. In multivariate analysis, BD and occurrence of >5 uveitis flares before anti-TNF initiation were associated with complete response to anti-TNF. BD was associated with increased odds of response. IFX and ADA appeared to be equivalent in terms of efficacy (Vallet et al, 2016*).

More recently, a retrospective observational study on 40 BD patients (66 eyes involved) receiving ADA found that the number of ocular flares significantly decreased from 200 flares/100 patients/year during the 12 months preceding ADA to 8.5 flares/100 patients/year during the 12 months following the start of therapy. Moreover, central macular thickness significantly improved at 12 month follow-up compared to baseline, while the number of patients with retinal vasculitis significantly decreased. The best corrected visual acuity also improved during the study period (Fabiani et al, 2017a*).

Also IL-1 inhibition with canakinumab and anakinra have recently proved to be possible therapeutic choices in patients showing a lack of response to other therapies. A recent multicentre retrospective observational study conducted on 19 consecutive BD patients (31 affected eyes) found a significant decrease of intra ocular flares during a 12-month follow-up period compared to the 12 preceding months. Similarly, the frequency of retinal vasculitis decreased both at 3- and 12-month follow-up evaluation. A significant steroid sparing effect was highlighted and no differences were identified between patients previously administered with other biologics and those undergoing IL-1 inhibition as first biologic approach (Fabiani et al, 2017b*). In addition to this study, a long series of case reports and case series had underlined the efficacy and safety of anakinra and canakinumab in ocular BD manifestations (Vitale et al, 2016b*). In this regard, also the anti-IL-1 β gevokizumab has proved to induced good results with a single intravenous infusion at the dosage of 0.3 mg/kg with rapid and complete

resolution of ocular inflammation within 21 days. Moreover, 5 patients re-treated with a second dosage maintained their response for several months (Gül et al, 2012*). A phase 2 trial on 21 BD patients suffering from posterior uveitis confirmed previous results by using gevokizumab at a dose of 30 or 60 mg every 4 weeks (Tugal-Tutkun et al, 2017*). However, although a preserved visual acuity and a less severe ocular inflammation were reported in patients undergoing gevokizumab, this biologic agent failed to meet the primary endpoint represented by the time to the first acute ocular exacerbation in a recent phase 3 randomised placebo controlled trial.

Alternatively, interferon α could be used instead (Kotter et al, 2004*). The efficacy of CsA versus IFX has been compared in the early phase of treatments in refractory uveitis in BD. In a retrospective study, 17 patients receiving monotherapy with IFX were compared with 20 patients treated with CsA (also without other concomitant immunosuppressive drugs). During the 6 months after starting the treatments, the number of episodes for each patient was 0.4 ± 1.0 in the infliximab group and 1.2 ± 1.2 in the CsA group ($p < 0.05$). Additionally, 82% of patients remained relapse-free in the group treated with IFX during the 6-month treatment period, compared with 45% of patients in the group treated with CsA (Yamada et al, 2010*).

IL-6 inhibition along with rituximab and the humanized monoclonal antibody against CD52 alemtuzumab represent further possible therapies for ocular BD, but to date this is mostly a field for clinical research (Lopalco et al, 2017*; Pelegrin et al, 2014*; Mohammad et al, 2015*).

1.15.4 Major vessel disease

There is no firm evidence to guide us in the management of major vessel disease in BD. For the management of acute large deep vein thrombosis in BD, glucocorticoids and immunosuppressive agents like AZA, cyclophosphamide (CYC) or CsA are recommended. For the management of arterial aneurysms and/or occlusion, according to EULAR recommendations, CYC and glucocorticoids are recommended (Hatemi et al, 2008*). For patients with BD and major vessel thrombosis, there is no consensus about giving anticoagulation, antiplatelet, or antifibrinolytic agents, or about the duration of anticoagulation. There are no controlled data or evidence of benefit of anticoagulants in the management of deep vein thrombosis of BD. Some authors recommend anticoagulants, whereas others suggest they should be avoided owing to the increased risk of fatal bleeding from coexisting pulmonary arterial aneurysm and an estimated low risk of pulmonary embolism in BD. According to a study on a large cohort of BD patients with vascular involvement, almost all patients with BD with deep vein thrombosis received anticoagulation therapy despite a high number ($n = 44$, 14.9%) of associated arterial aneurysms, of whom eight had pulmonary arterial aneurysms. The tolerance was satisfactory, with 2% of haemorrhagic complications. In addition, a previous study claimed that immunosuppressive agents significantly reduce venous thrombosis relapse in BD (Desbois et al, 2012*).

According to a recent open-label, single-arm phase 3 study involving 4 BD patients with active vascular lesions and poor response or intolerance to conventional therapy, IFX allowed clinical and laboratory improvement after 2 weeks of therapy, while imaging findings showed reversal of inflammatory changes in 3 out of 4 patients, thus supporting IFX as a new therapeutic option for patients with vascular BD (Hibi et al, 2016*). Similarly, in another study TNF α inhibition with IFX or ADA proved to improve cardiovascular manifestations in 4 out of 6 cases with diverse BD-related vascular features.

1.15.5 Neurological involvement

No controlled data guide the management of CNS involvement in BD. For patients with parenchymal neuro-Behçet's disease without any poor prognostic factor, AZA and glucocorticoids are usually prescribed as first-line treatment. For patients with more severe disease, intravenous CYC and glucocorticoids are recommended. If these regimens fail, TNF α -blocking drugs, such as IFX, should be added. For dural sinus thrombosis, glucocorticoids and anticoagulation are recommended. In a multicentre study including 17 BD patients with symptomatic parenchymal NBD, refractory to previous immunosuppressant and treated with anti-TNF α (infliximab 5 mg/kg [n=13] or adalimumab [n=4]), overall improvement following anti-TNF was evidenced in 16/17 (94.1%) patients including 6 (35.3%) complete response and 10 (58.8%) partial response. The median time to achieve remission was 3 months (Desbois et al, 2016*). Vallet et al evaluated IFX and ADA in 13 patients with NBD and meningo-encephalitis or rhombencephalitis, highlighting an overall improvement in 12 cases with TNF α inhibition (Vallet et al, 2015*).

IL-6 inhibition represents a promising therapeutic option for NBD. Indeed, IL-6 levels in cerebrospinal fluid have been found higher in patients with active NBD compared to unaffected controls. In addition, IL-6 levels are more elevated in cerebrospinal fluid of patients with acute NBD than in subjects with chronic neurological involvement, thus suggesting a direct involvement of IL-6 in neurological BD activity. In this context, tocilizumab infusions at 8 mg/kg every 4 weeks induced a prompt and sustained response with significant steroid tapering in 3 patients with parenchymal BD involvement. Although a loss of efficacy occurred after 18 months in one patient, the shortening of the interval between the infusions allowed a recovery of benefits (Addimanda et al, 2015*).

A recent case series claimed intravenous immunoglobulin treatment as a useful possibility in NBD unresponsive to conventional treatment or when clinical data do not allow a well-defined differential diagnosis with multiple sclerosis (Cantarini et al, 2016*).

1.15.6 Gastrointestinal disease

No evidence-based treatment can be recommended for the management of gastrointestinal involvement in BD. Sulfasalazine and 5-aminosalicylate are used empirically but might maintain remission in entero-BD. In a

retrospective study this treatment was found to maintain remission in 143 Korean patients with entero-BD (Jung et al, 2012*). An observational study has suggested 5-aminosalicylate as a valuable treatment for preventing postoperative recurrences (Hatemi et al, 2016*). Agents such as glucocorticoids, AZA and/or TNF antagonists should be tried first before surgery, except in an emergency (perforation).

Among TNF inhibitors, IFX is adopted from the regimen employed for Crohn disease (5 mg/kg intravenous at weeks 0, 2, and 6). A recent open-label single-arm phase 3 study conducted on 18 BD patients including 11 with gastrointestinal manifestations claimed that IFX is able to induce clinical improvement and decrease of inflammatory markers at 2-week follow-up (Kinoshita et al, 2013*). According to a Korean multicentre retrospective study on 28 patients treated with IFX, clinical response was obtained in 64.3% of patients and clinical remission in 28.6% at 4 week evaluation after IFX infusion (Lee et al, 2013*). Another retrospective study on 15 patients with refractory gastrointestinal involvement treated with IFX administered every eight weeks at the dosage of 5 mg/kg observed a good response to in 80% of cases and remission in 53% after 10 weeks. The percentage of patients maintaining the response at 12 and 24 months was 64% and 50%, respectively (Habit et al, 2016*).

Although current data on ADA efficacy in gastrointestinal BD are few, an increasing number of studies are proving the usefulness of ADA on gastrointestinal involvement. In particular, a phase 3, multicentre, open-label uncontrolled study on 20 Japanese patients with active and resistant intestinal BD showed that ADA administered at induction schedule of 160 mg at baseline, 80 mg at week 2 followed by 40 mg every other week induced an improvement of symptoms and endoscopic findings in 60% of patients at 52-week follow-up, while 20% of patients reached a complete remission (Tanida et al, 2015*). These data are supported also by retrospective studies (Vallet et al, 2015*).

Less experience has been gained on the use of etanercept for the management of gastrointestinal BD; however, current evidences suggest a better effect of etanercept compared to conventional therapies (Ma et al, 2014*).

Regarding the use of IL-1 inhibition on gastrointestinal involvement, although encouraging, current data are limited to case reports.

1.15.7 Comments on current management

A multidisciplinary expert committee has published the EULAR recommendations for the management of BD (Hatemi et al, 2009*). Recommendations related to eye and skin/mucosal disease and arthritis were mainly evidence based, whereas recommendations related to vascular disease and neurological and gastrointestinal involvement were based on expert opinion and on uncontrolled evidence from open trials and observational studies. Nine recommendations were developed and are presented in table 4.

Table 6 EULAR recommendations for the management of Behçet's disease. (Reproduced from Hatemi et al, *Ann Rheum Dis* 2009;68:1528–34*)

No.	Recommendation
1	Any patient with BD and inflammatory eye disease affecting the posterior segment should be following a treatment regimen that includes azathioprine and systemic glucocorticoids
2	If the patient has severe eye disease defined as >2 lines of drop in visual acuity on a 10/10 scale and/or retinal disease (retinal vasculitis or macular involvement), it is recommended that either cyclosporine A or infliximab be used in combination with azathioprine and glucocorticoids; alternatively, IFN α with glucocorticoids may be used
3	There is no firm evidence to guide the management of major vessel disease in BD. For the management of acute deep vein thrombosis in BD, immunosuppressive agents such as glucocorticoids, azathioprine, CYC or cyclosporine A are recommended. For the management of pulmonary and peripheral arterial aneurysms, CYC and glucocorticoids are recommended
4	Similarly, there are no controlled data on, or evidence of, benefit from uncontrolled treatment with anticoagulants or antiplatelet or fibrinolytic agents in the management of deep vein thrombosis or for the use of anticoagulation for the arterial lesions of BD
5	No evidence-based treatment can be recommended for the management of gastrointestinal involvement of BD. Agents such as sulfasalazine, glucocorticoids, azathioprine, TNF α antagonists and thalidomide should be tried first before surgery, except in emergencies
6	In most patients with BD, arthritis can be managed with colchicine
7	There are no controlled data to guide the management of CNS involvement in BD. For parenchymal involvement, glucocorticoids, IFN α , azathioprine, CYC, methotrexate and TNF α antagonists may be tried. For dural sinus thrombosis glucocorticoids are recommended
8	Cyclosporine A should not be used in patients with BD with CNS involvement unless necessary for intraocular inflammation
9	The decision to treat skin and mucosa involvement will depend on the perceived severity by the doctor and the patient. Mucocutaneous involvement should be treated according to the dominant or co-dominant lesions present
	Topical measures (i.e., local glucocorticoids) should be the first line of treatment for isolated oral and genital ulcers
	Acne-like lesions are usually of cosmetic concern only. Thus, topical measures as used in acne vulgaris are sufficient
	Colchicine should be preferred when the dominant lesion is erythema nodosum
	Leg ulcers in BD might have different causes. Treatment should be planned accordingly
	Azathioprine, IFN α and TNF α antagonists may be considered in resistant cases

BD, Behçet's disease; CNS, central nervous system; CYC, cyclophosphamide; IFN, interferon; TNF, tumour necrosis factor.

During recent decades, therapeutic strategy in BD has become more intensive with the use of immunosuppressive agents. Although new immunomodulatory therapies seem to be highly effective in uncontrolled studies and seem to have a rapid onset of action in different clinical situations, no consensus exists about their use in BD. Refractory manifestations that may warrant immunomodulatory treatment include severe ocular disease, CNS, and vascular involvement and some severe or refractory gastrointestinal, joint and mucocutaneous involvement.

However, TNF inhibition has got ahead as useful treatment for the protean clinical spectrum of BD. In addition to IFX and ADA, also other anti-TNF agents are taking up a space. In this regard, a recent retrospective observational study found golimumab as a useful therapeutic choice in multisystem resistant BD. In particular, golimumab was capable of controlling disease manifestations found at the start of therapy and reducing global disease activity (Vitale et al, 2017b).

Also other agents have been indicated as potential useful therapeutic choices, including the inhibitors of IL-1, IL-6, CD52, intravenous immunoglobulins and apremilast. Nevertheless, clinical research is required in order to establish which subgroup of patients should be firstly treated with these agents, what are the optimal dosages and intervals of administration.

1.16 Prognosis and impact on quality of life

Mortality and morbidity are high in young male patients with BD. Women have less severe disease than men. The main causes of death are major vessel disease and, particularly, pulmonary artery aneurysms and neurological involvement (Kural-Seyahi et al, 2003*). The disease typically abates after 40 years of age, but CNS involvement and major vessel disease may have a late onset (5–10 years after diagnosis). The death rate, quite different from that seen in systemic lupus erythematosus and rheumatoid arthritis, decreases in BD along the disease course. This might be related to (a) self-abating disease activity and (b) an absence of accelerated atherosclerosis, which is well known to be associated with the increased late death rates in classic autoimmune diseases. Both these points seem to be true for BD. Many patients from an initial cohort with BD would not fulfil any of the diagnostic criteria when surveyed 20 years later and preliminary evidence does not indicate accelerated atherosclerosis in BD.

A study of pulmonary arterial aneurysms has shown that the death rate has decreased from 50% to around 20% in the past decade owing to earlier recognition or better use of immunosuppressive agents.

Eye inflammation and greatest eye damage occur during the first 2 years. Loss of useful vision ensues in about 20% of patients despite treatment.

A retrospective study reporting the 10-year visual outcome of 39 patients with uveitis showed progressive eye disease and a visual acuity of <0.1 in 39% of affected eyes in spite of the multitude of available treatments. However, drug use during this period suggested that these patients might have been undertreated, as colchicine, CsA and glucocorticoids were the most frequently used agents and seven patients used only one drug (colchicine n = 5, CsA n = 2).

Regarding the impact on patient's life, BD is capable of significantly decreasing quality of life. Interestingly, although BD is usually more severe among men patients, the impact of BD seems to be higher among women. This evidence probably reflects social and physiological differences between males and females as well as a

different aptitude to BD acceptance. The impact of BD on quality of life is closely related to the overall disease activity; however, single organ involvements may also affect quality of life in an independent fashion, especially in relation to mucosal, NBD, musculoskeletal, and ocular manifestations. Concerning ocular involvement, quality of life is impaired especially in patients with panuveitis compared to other BD-related ocular manifestations and is inversely correlated with the best corrected visual acuity (Fabiani et al, 2017*).

SUMMARY POINTS - Behçet's disease

- ➔ **Behçet's disease (BD) is an inflammatory disease that runs a relapsing and remitting course.**
- ➔ **BD has a geographical predilection and is seen more frequently in the Mediterranean basin and the Far East.**
- ➔ **Mucocutaneous manifestations, uveitis and articular manifestations are more common than peripheral arterial disease, venous thromboses, and neurological and gastrointestinal involvement.**
- ➔ **Young males have more severe disease.**
- ➔ **The use of immunosuppressive agents has undoubtedly provided an improvement in the management of severe BD**
- ➔ **Tumour Necrosis Factor inhibition has improved the management of sight- and life-threatening BD manifestations**
- ➔ **Inhibition of interleukin(IL)-1 and IL-6 represent promising therapeutic options in BD patients**

2 Relapsing polychondritis

Relapsing polychondritis (RP) is a rare autoimmune condition characterised by recurrent episodes of inflammation of cartilage, especially of the ears, nose and tracheobronchial tree. It has a variety of organ system involvement, including the joints, heart and kidney. It may occur alone (primary) or can be associated with a long list of conditions (secondary) (table 1). It has also been proposed that it “is not a primary disease, but a syndrome associated with multiple precipitating factors that appear in a genetically susceptible subject”. RP may have a rather benign course or, alternatively, a very severe course ending in death.

Table 1 Systemic diseases associated with relapsing polychondritis

Systemic vasculitides	Connective tissue diseases	Blood dyscrasias	Autoimmune and other conditions
Behçet's disease	Rheumatoid arthritis	Myelodysplastic syndrome	Vitiligo
Wegener's granulomatosis	Systemic lupus erythematosus	Haematological malignancies	Autoimmune thyroid disease
Polyarteritis nodosa	Sjögren's syndrome	Cryoglobulinaemia	Myasthenia gravis
Takayasu's arteritis	Juvenile chronic arthritis	Pernicious anaemia	Primary biliary cirrhosis
Leucocytoclastic vasculitis	Antiphospholipid syndrome	Thymoma	Dermatitis herpetiformis
Cogan's syndrome			Atopic dermatitis
Henoch–Schönlein purpura			
Thromboangiitis obliterans			Lichen planus
			Psoriasis
			Glomerulonephritis
			Inflammatory bowel disease
			Diabetes mellitus
			FMF
			Panniculitis
			Retroperitoneal fibrosis
			Spondylarthritides
			Sweet's syndrome

FMF, *familial Mediterranean fever*.

2.1 Epidemiology and genetics

RP is distinctly rare, with an estimated incidence of 3.5 cases per million/year; male and female subjects are equally affected. The peak incidence is in the fifth decade, but it can also occur in children and in older adults. The association with other autoimmune disorders, myelodysplasia and/or systemic inflammatory conditions is found in 25–30% of adult patients with RP (Kent et al, 2004*). No ethnic or familial clustering has been noted. However, there is an increased frequency of HLA-DR4 among patients.

2.2 Clinical findings

The usual onset is abrupt and relapses occur in the course of the disease. In the secondary forms the associated condition has usually been present for some time before RP onset.

Table 2 summarises the various clinical findings, with their approximate frequency at presentation or during the disease course. It is to be noted that almost all organs can be affected by either the primary or the secondary form.

Table 2 Clinical manifestations of relapsing polychondritis. (Adapted from Kent et al, *Curr Opin Rheumatol* 2004;16:56–61*)

Feature	Frequency (%)	
	At presentation	During course
Auricular chondritis	45	90
Arthritis	30	70
Nasal chondritis	20	60
Ocular disease	20	60
Laryngotracheal involvement	20	55
Reduced hearing and/or vestibular dysfunction	5	40
Skin–mucosa	5	30
Kidney disease	5	25
Heart disease	0	10
Vasculitis	2	15

The most common presenting symptom of RP (~50%) is inflammation of the external ear, which can be unilateral or bilateral. In a patient with inflammation in one ear, this is usually not attributed to a systemic disease, especially in the primary form where there is no associated disease to alert the patient or the physician. Often the inflammation is ascribed to infection and antibiotics are prescribed. However, one should search for recent local infection if the involvement is unilateral. Also frostbite or burns—including ultraviolet—can cause such inflammation in the external ear, even weeks after the original trauma.

The auricular portion of the external ear is inflamed in RP but the earlobes, which do not have cartilage, are spared. With continuing inflammation, the auricular portions become flabby (figure 1) as the cartilage matrix is destroyed.

Disease can also occur in the ear and related structures. The Eustachian tubes may close, leading to hearing loss and otitis. Associated arteritis of the internal auditory artery can sometimes cause tinnitus and vertigo due to impaired cochlear blood supply.

Figure 1 Earlobe destruction in relapsing polychondritis. (Image courtesy of Professor Ina Kötter, Tübingen, Germany)

The presence of additional sites of inflammation helps diagnosis. Nasal cartilage is the most common second site, involved in up to 54% of patients. There is pain, local tenderness and, if it progresses, a saddle nose deformity may result, especially in patients aged less than 50 years and in females. The nose feels stuffy and the patient may complain of frequent nose bleeds or serosanguinous exudation.

A laryngotracheobronchial disease appears in nearly half of RP patients and can be life-threatening as represents the main cause of death. The initial symptoms are hoarseness, non-productive cough, stridor and wheezing together with tenderness over the larynx and trachea. Upper airway obstruction necessitates emergency tracheostomy. Diseased cartilaginous structures of the lower airways can cause repeated bouts of pneumonia by interfering with normal drainage in the lungs. However, pulmonary infiltrates may also be related to an underlying vasculitis accompanying RP.

RP does not usually involve articular cartilage (see section 2.6) apart from the fibrocartilaginous costochondral joints, mimicking Tietze syndrome, a common and benign condition, causing local sternal pain. In rare instances the sternal disease may be more severe with involvement of the sternomanubrial and sternoclavicular joints with structural changes leading to pectus excavatus.

Even though articular cartilage is spared, arthritis is common in RP and can precede its onset by weeks or months. Indeed, it may be the presenting symptom in 33% of patients. It is a non-deforming, episodic oligoarthritis involving both large and small peripheral joints. Although the affected joints are warm and swollen, the synovial fluid is non-inflammatory.

Eye disease in RP can take many forms and affects over half of patients during the entire course of the disease. The most common lesions are episcleritis, scleritis and conjunctivitis. However, keratitis, corneal melt, uveitis, retinal vasculitis, and even periadnexal disease leading to proptosis, can be seen. Proptosis, lid oedema, iridocyclitis, retinopathy, optic neuritis and hypopyon uveitis, a feature typical for Behçet's disease (BD), are other possible manifestations as well as a vasculitis involving the extraocular muscles. MALT (mucosa-associated lymphoid tissue) lymphomas around the eye have also been described. Retinal disease can lead to visual loss.

Heart involvement is an integral part of the clinical picture in RP. It is seen in around 10% of patients with RP and its insidious and potentially sinister course necessitates due attention as represents the second most common cause of death in these patients. Cardiac involvement in RP can be due to valvular disease—notably, aortic with associated aortitis, coronary vasculitis (sometimes leading to myocardial infarction), problems with the conduction system and myocarditis or pericarditis (rare). In particular, aortic root involvement may develop years after the initial diagnosis and can progress despite immunosuppressive treatment administered for disease involvement at other sites and despite apparent RP remission. Also, aortic aneurysms occur frequently in RP in all parts of the aorta, possibly resulting in fatal rupture even in asymptomatic patients. Thus, it is important that patients with RP are followed up for developing murmurs, especially if congestive heart failure is present. Also a chest radiograph, an electrocardiogram and an echocardiogram should be part of the initial evaluation of a patient with RP, even in the absence of cardiovascular symptoms.

Arteries and veins of all sizes can also be affected. The aortic arch and the abdominal aorta can be diseased, with a clinical picture similar to Takayasu's arteritis; as with many other disease associations of RP, it is unclear whether cartilage inflammation in such patients is due to primary Takayasu's arteritis with secondary cartilage involvement or vice versa. Thrombosis of the large and small veins—as in BD—can also be seen. Aortic involvement is rare in RP, being encountered in 4–9% of the patients. It may lead to life-threatening complications, such as severe aortic insufficiency, active aortitis and aortic aneurysm (McAdam et al, 1976*).

Both the central nervous system (CNS) and the peripheral nerves can be involved by vasculitis resulting in heterogeneous manifestations such as headache, seizures, cortical lesions with pyramidal signs, aseptic

meningitis, meningoencephalitis, cerebral aneurysms and loss of cognitive function. The cranial nerves are the most commonly affected nerves of the CNS. Optic atrophy leading to visual loss and abducens paralysis resulting in loss of lateral gaze are the most frequent complications, followed by lesions in the seventh and eighth nerves. The CNS and peripheral neuropathy in RP has been ascribed to the generalised vasculitis seen in the primary and secondary forms, although this is seldom demonstrated.

Skin–mucosa involvement in RP can present in many forms. The most common lesions are recurrent oral ulcers, nodules on the limbs and purpura, while the most common histological finding is a leucocytoclastic vasculitis. A lot of other skin manifestations have been related to RP including urticarial-like lesions, erythema multiforme, erythema annulare centrifugum, erythema elevatum diutinum, skin panniculitis, actinic granulomas, and Sweet's syndrome (Cantarini et al, 2014*). About 90% of a subgroup of patients with RP characterised by the association of myelodysplastic syndrome, have skin disease. These patients are, on average, a decade or two older than other patients with RP, and some can present with fever of unknown origin. Notably, most patients with concomitant RP and Sweet syndrome show an association with malignancies, especially myelodysplastic syndromes (Diebold et al, 1995*).

Kidney involvement can be caused by primary renal parenchymal lesions, an underlying vasculitis (ranging from mesangial disease and IgA nephropathy to crescentic glomerulonephritis), or an associated autoimmune disorder. Although renal disease is quite rare, raised creatinine levels are reported in 10%, and abnormalities in urine analysis in 26%. However, renal disease indicated a worse prognosis, with a 10-year survival of 30% (Chang-Miller et al, 1987*).

The so-called MAGIC syndrome (mouth and genital ulcers with inflamed cartilage) is probably similar to that in BD with secondary RP.

2.3 Laboratory findings

No laboratory findings are specific for RP, and patients with secondary forms can show the more specific findings, if any, of the associated diseases. An augmented acute phase response is seen in most patients. Most patients show normocytic normochromic anemia, leukocytosis, thrombocytosis, and polyclonal hypergammaglobulinemia. Antibodies to native collagen II, present in about 50% of patients, are only used in research and are not sufficiently specific to be diagnostically useful. Up to 66% of patients show the presence of antinuclear antibodies (ANA), usually in a low titer and with a speckled pattern. This finding suggests the presence of a concomitant associated autoimmune disorder. Also anti-neutrophil cytoplasmic antibodies (ANCA) may be found, especially during the active phase of the disease.

2.4 Imaging

Radiographs may highlight calcific deposits in auricular, nasal or tracheal cartilage in patients with long-lasting disease. Computed tomography (CT) is useful in detecting early involvement of the upper airways as well as bronchial cartilage damage up to lobar and segmental bronchi. Morphological changes including wall thickness with or without calcifications and fixed narrowed airway along with increased airway wall attenuation and smooth diffuse thickening represent the most frequently encountered findings. Enlarged mediastinal lymph nodes can also be found. Magnetic resonance imaging (MRI) plays a major role in identifying inflammation of perichondrium and chondroepiphysis. MRI is also used to demonstrate the blood-endolymph barrier breakdown in cases with inner ear involvement. Positron emission tomography (PET)/CT may identify multi-systemic cartilaginous abnormalities and is also considered a useful tool for assessing disease activity and response to treatment. In addition Moreover, PET/CT provides advantages for an adequate targeted biotic procedure (Cantarini et al, 2014*).

End bronchial ultrasound allows the identification of airway chondritis and echocardiography is used to assess cardiac valves and aortic root in cases of cardiovascular involvement. Careful attention should be paid to bronchoscopy, which may exacerbate airway inflammation and is difficult in patients with small glottis due to cartilage destruction.

2.5 Diagnosis and differential diagnosis

Over the years, several sets of criteria have been proposed for diagnosis, all based on combinations of the spread of involvement of cartilaginous sites and the common clinical findings of the associated diseases. To date, diagnosis is based on criteria suggested by McAdams et al. in 1976 (McAdams et al, 1976*), later refined and improved by Damiani et al. (Damiani et al, 1979*) and Michet et al. (Michet et al, 1986*) Table 3 illustrates the diagnostic criteria proposed for RP. Anyway, as is true for all rare diseases, formulating 'diagnostic' criteria that are useful in an individual patient is probably also unrealistic in RP. The very low pre-test probability makes the likelihood of false positives unacceptably high even with criteria that have very high specificity and sensitivity. In the clinical setting, symmetrical cartilage involvement in the ears with an additional site of cartilage disease is usually adequate for diagnosis. Only in doubtful cases should one resort to histological diagnosis.

Table 3 shows diagnostic criteria currently employed for diagnosing relapsing polychondritis. The table has been adapted from Vitale et al, 2016.

Criteria	Items	Requirements for diagnosis
McAdam et al	<ul style="list-style-type: none"> - Bilateral auricular chondritis - Nasal chondritis - Respiratory tract chondritis - Non-erosive seronegative polyarthrititis - Ocular inflammation - Audiovestibular damage 	At least three items fulfilled
Damiani et al	<ul style="list-style-type: none"> - McAdam items - Histologic confirmation - Positive response to corticosteroids or dapsone 	At least three McAdam items fulfilled Or One McAdam criteria in addition to histologic confirmation Or Two McAdam items fulfilled in addition to effectiveness of corticosteroids or dapsone
Michet et al	Items A <ul style="list-style-type: none"> - Auricular cartilage inflammation - Nasal cartilage inflammation - Laryngotracheal cartilage inflammation Items B <ul style="list-style-type: none"> - Ocular inflammation - Hearing loss - Vestibular dysfunction - Sero-negative arthritis 	At least two items "A" Or At least one item "A" plus at least two items "B"

2.5.1 Ear problems

The foremost consideration in ear problems is bacterial or fungal infection, especially when the involvement is unilateral. Sparing of the ear lobes in RP and the presence of enlarged lymph nodes in infection are helpful.

Insect bites, chemical and physical trauma such as frostbite and sunburn are other considerations and it should be borne in mind that it might sometimes take weeks after the initial trauma before the ear inflammation begins.

2.5.2 Nasal findings

Indolent infections with mycobacteria (both tuberculosis and leprosy), leishmaniosis, syphilis and fungi, in particular, can cause damage to the nasal cartilage. Systemic lupus Erythematosus, Wegener's granulomatosis,

sarcoidosis and lymphomatous involvement in midline granuloma are other considerations. Sparing of the mucosa and the relative paucity of surrounding inflammation in RP might be helpful in diagnosis. Nasal deformation can occur after trauma and long-term cocaine inhalation.

2.5.3 Eye involvement

Episcleritis, scleritis, keratitis and uveitis can be seen both in primary RP and as part of the clinical spectrum of the long list of associated conditions. Important points to consider here are (a) scleritis and keratitis are unusual in BD, while episcleritis and hypopyon can be seen; (b) uveitis is not part of rheumatoid arthritis; (c) Wegener's granulomatosis can cause all the ophthalmic findings of RP and in addition proptosis, which can be seen in both Wegener's disease and RP. Interstitial keratitis is an integral part of Cogan's syndrome, which, with its vestibular neuritis, can be difficult to tell apart from RP.

2.5.4 Laryngotracheal involvement

Tracheal involvement is a very useful finding in differential diagnosis because, apart from direct trauma (eg, as a complication of intubation) and Wegener's disease (granulomatosis with polyangiitis), no other diseases cause a similar problem. However, also amyloidosis and sarcoidosis should be taken in mind in case of subglottic stenosis.

2.5.5 Articular involvement

When articular involvement is the presenting symptom, a mistaken diagnosis with rheumatoid arthritis may be possible. RP may be also misdiagnosis with spondyloarthritis when articular and ocular symptoms coexist. However, unlike rheumatoid arthritis, joint involvement is generally non-deforming, non-erosive, and synovial liquid analysis shows a not-so-clear inflammatory picture. In addition, spondyloarthritis is generally associated with anterior uveitis.

2.5.5 Aortic involvement

Enlargement of the aortic root can also be seen in ankylosing spondylitis, Marfan or Ehlers–Danlos syndrome. Also Takayasu's arteritis and polyarteritis nodosa may present with aortic aneurysms, but they are not primarily characterized by cartilage involvement.

2.6 Evaluation of disease activity

No laboratory markers exist to evaluate the entity of cartilage damage and disease activity in clinical practice and current proposals are mainly confined to laboratory research. Conversely, based on clinical evaluation, an international collaboration involving 27 experts proposed the Relapsing Polychondritis Disease Activity Index (RPDAI), a clinometric tool based on 27 items with individual weights ranging from 1 to 24 and a maximum

theoretical score of 265. The RPDAI should be filled taking into account the 28 days preceding the medical examination (Arnaud et al, 2012*).

2.7 Pathology

No biopsy findings are pathognomonic for the diagnosis of RP and biopsies of the nose, ear or other involved cartilages provide useful information only in a minority of cases. However, histopathological examination may be taken into account when the diagnosis is puzzling.

The early and active lesions in the cartilage show infiltration with lymphocytes (mainly CD4) together with neutrophils, mononuclear and plasma cells in variable proportions. C3 and immunoglobulin deposition may also be found. This is followed in time by more immunoglobulin and complement deposition with increasing amounts of cartilage destruction. The chondrocytes initially phagocytose the degraded material and later they themselves degenerate. A loss of basophilic staining of the cartilage matrix and capillary endothelial cell proliferation are also observed on biopsies. The final stages show fibrosis with focal areas of calcification, gelatinous cysts and new bone formation.

Chronic synovitis is seen only at the diarthrodial joints on the hand. Aortitis is characterised by mononuclear cell infiltration with destruction of the collagen and elastic fibres. The inflammation can involve the whole arterial wall and lead to aneurysm formation.

Kidney involvement can range from mild mesangial disease to IgA nephropathy or segmental crescentic glomerulonephritis, mostly representing the pathological landmarks of the associated diseases.

2.8 Pathogenesis

The exact pathogenesis of RP is not known but an autoimmune mechanism is strongly implicated. The evidence for this is several fold:

- The histology of the involved tissue as discussed above.
- A frequent association with other autoimmune disorders.
- Matrilin 1 is a cartilage matrix protein prominent in tracheal, auricular and nasal cartilages. Injection of this protein into mice causes a clinical picture quite similar to RP and antibodies to the same have been described in human disease.
- About half of patients with RP develop antibodies to native collagen type II, found in abundance in cartilage and sclera. Furthermore, immunising DQ8 and HLA-DQ6 double transgenic mice with collagen type II can induce chondritis in these animals.
- Humoral and cellular reactivity against collagen type IX and XI have also been observed.

- The frequency of HLA-DR4—an allele associated with several autoimmune diseases, including rheumatoid arthritis—is increased among patients with RP.
- Finally, cartilage is considered to be an immunologically privileged site like the eye, so there is no immunological tolerance to its structural proteins in the healthy organism. This, in turn, makes the cartilage prone to an autoimmune insult after different noxae including trauma, toxins or infectious diseases. Thus, the cartilage damage seen in RP associated with many autoimmune/autoinflammatory diseases may be similar to the uveal disease seen in some of these conditions as well.

Hormonal factors have also been postulated, as RP can be triggered during pregnancy.

2.9 Management

Owing to the rarity of the condition and perhaps to the association with many other diseases, there are no evidence-based treatment options for managing RP. Treatment is mainly based on published expert opinion which, in turn, is based on uncontrolled observations.

However, management is tailored to disease extent and severity. If involvement is limited to the external ear and the cartilage of the nose, with no apparent destructive changes or arthritis, treatment with non-steroidal anti-inflammatory drugs may be all that is required. A second choice would be dapsone (50–200 mg/day). Still others prefer small doses of steroids (10–20 mg prednisone/day) in this setting.

More destructive changes in the cartilage or laryngotracheal, vestibuloneural, lung, eye, heart or kidney involvement or systemic vasculitis require higher doses of steroids (prednisone at ~60 mg/day). Long-term steroid therapy represents the mainstay option in order to decrease the severity and frequency of disease bouts. Disease modifying anti-rheumatic drugs (DMARDs) are useful in resistant cases and as corticosteroid-sparing agents. In particular, cyclophosphamide at 1–2 mg/kg/day is usually added in more severe, life-threatening lung, heart or kidney disease. Azathioprine, methotrexate or cyclosporine A (with due attention to kidney function) can also be used either as remission-inducing or steroid-sparing additional treatment. Patients resistant to other treatment may respond to biologic agents. To date, TNF α inhibitors represent the most commonly described agents for the treatment of RP and are regarded the ideal treatment in case of nonresponsive central nervous system involvement. Current experience with TNF α inhibitors mainly deal with infliximab, adalimumab and etanercept (Vitale et al, 2015*). In particular, according to a case series reporting on 9 patients treated with twenty-two biologic courses, anti-TNF α -agents used led to partial or complete disease control in 6 out of 7 cases treated with TNF α inhibition. However, a loss of efficacy was recorded in 5 cases, obligating to switch to a second TNF α inhibitor or to another biologic agent. In this context, the cytotoxic T lymphocyte antigen 4-immunoglobulin abatacept and the anti-IL-6 agent tocilizumab proved to be effective as second-line biologics, while the anti-interleukin(IL)-1 receptor antagonist anakinra brought about poor results (Moulis et al, 2013*).

Anyway, cases unresponsive to anti-TNF α drugs are widely described as well as patients reporting severe adverse events soon after the start of treatment, including infections, a fulminant necrotizing eosinophilic myocarditis and the occurrence of Sweet syndrome (Adamson et al, 2013*; Moore et al, 2014*). Of note, a case report claimed that RP may also develop as a paradoxical effect of anti-TNF therapy (Hernández et al, 2011*).

Regarding abatacept, data currently available are quite conflicting and support the use of this agent especially in patients with joint involvement and ear, nose and throat chondritis. Notably, the intravenous formulation seems better than the subcutaneous administration (Peng et al, 2013*). Similarly, contrasting results are published on the IL-6 receptor antagonist tocilizumab, whose use could be limited to RP patients with elevated serum IL-6 levels (Wendling et al, 2013*). However, tocilizumab has been reported to be effective in patients with refractory RP-related aortitis (Loricera et al, 2014*; Stael et al, 2015*).

Also the IL-1 receptor antagonist anakinra and the anti-CD20 agent rituximab have proved to induce clinical remission in some cases and no clinical results in others (Vitale et al, 2015*).

Non-pharmacological treatment of RP is primarily focused on the management of airway lesions. A laryngotracheobronchial involvement appears in nearly half of patients and is complicated by local obstructions, which may be life threatening. Consequently, involvement of the cartilaginous structures of the airways may require physical measures, which include continuous positive airway pressure, especially at night, and surgical procedures including tracheostomy, stenting, airway dilatation, laser extirpation and laryngotracheal reconstruction.

As discussed, cardiac valvular involvement may be insidious and resistant to treatment. In patients undergoing aortic valve replacement, it is also advisable to insert a synthetic graft in the ascending aorta to minimise postoperative aneurysm formation and valvular leaks.

Plastic surgery on auricular and nasal structures may have a role for aesthetic reasons in order to solve cartilage deformities.

2.10 Prognosis

Two decades ago, the reported 10-year survival was 55% in a case series, while a more recent figure puts this close to 95%. Increased general awareness, with recognition of milder cases, probably plays an important role in this improved survival. Prognosis depends on specific organ involvement and response to treatment. The prognosis is poor for patients displaying respiratory tract involvement. In Michet's series, infection (mainly pneumonia, but also cellulitis, bacteraemia, abscess), airway collapse or obstruction and cardiovascular complications were the major causes of death. In patients aged ≤ 50 years, anaemia, saddle nose deformity, vasculitis, arthritis, laryngotracheal stenosis and microhaematuria at the time of diagnosis were associated with an increased risk of death. In patients aged > 50 years, anaemia was the only prognostic factor associated with a

higher mortality. Patients who have both RP and systemic vasculitis have been reported to have a 5-year survival rate of 45%, and usually die from vasculitis rather than from other complications of RP.

SUMMARY POINTS - Relapsing polychondritis

- ➔ Relapsing polychondritis (RP) is an acute-onset, relapsing inflammation of the cartilage, but a multiorgan damage is possible.
- ➔ RP may occur together with a primary disease but may also be a primary disease itself.
- ➔ Major sites of involvement are the auricular and nasal cartilages and eyes.
- ➔ Arthritis is also common.
- ➔ Relapsing polychondritis is generally not life threatening unless it involves laryngotracheal cartilage or major artery roots.
- ➔ Immunosuppression to prevent relapses is the mainstay of treatment.

3 Eye symptoms in rheumatic diseases

Autoimmune disorders can have severe systemic and ocular effects, so an early diagnosis is key to successful treatment and better prognosis.

Ocular symptoms may include dry or red eyes, pruritus, photophobia, pain, foreign body sensation, visual changes and even complete loss of vision. Because a number of these conditions may initially present with non-specific ocular manifestations, physicians should keep in mind that they might be the presenting symptom of active, potentially fatal systemic disease, despite their vague character (Harper and Foster, 1998*).

Therefore, in any patient with a rheumatic disease who has ocular symptoms, a thorough ophthalmic examination, including ocular motility, pupillary reaction, visual acuity, visual field testing, external inspection with the slit lamp, corneal staining with fluorescein and direct or indirect ophthalmoscopy, should be sought. In dry eye syndrome, simple tools such as Schirmer's test or the break-up time of the tear film can be useful in diagnosis.

3.1 Ophthalmological manifestations

3.1.1 Keratoconjunctivitis sicca

Keratoconjunctivitis sicca (KCS), also known as dry eye disease, is a multifactorial affection of the tears and ocular surface resulting in tear film instability, ocular discomfort, visual disturbance and potential damage of ocular surface. Patients with dry eye syndrome mostly complain of dryness, foreign body sensation, burning, grittiness, blurred vision and blepharospasm. The symptoms are more prominent in the morning, owing to incomplete lid closure during the night, and during the latter part of the day because of evaporation of the tear film. Of note, discordance between patients' symptomatology and the severity of ocular surface clinical signs is frequent.

Triggering factors for (KCS) include older age, female sex, local environment, use of video display, smoking, contact lens wear and exposure to specific treatments such as antidepressants, antihistamines, antipsychotics, and diuretics. Hormonal condition play an important role in dry eye disease as peri- and postmenopausal females are especially affected. In addition, hormones influence aqueous tear secretion, meibomian gland function, and conjunctival goblet cell density. However, despite aetiology, surface inflammatory events and tear hyperosmolarity are universally accepted as the turning point of pathogenesis in inducing qualitative and quantitative changes in tears.

Currently, two subgroups of dry eye disease are recognized: aqueous deficient and evaporative. The former subgroup refers chiefly to a failure of lacrimal secretion due to lacrimal acinar destruction or dysfunction, which in turn causes hyperosmolarity as a stimulus for inflammatory pathways. Conversely, the evaporative dry eye is related to an excessive water loss from the exposed ocular surface in subjects with normal lacrimal secretory function.

Sjögren's syndrome, which represents the prototype of autoimmune induced dry eye in the rheumatologic context, is a large part of the aqueous tear-deficient subtype. Sjögren's syndrome may be a primary autoimmune disorders or secondary to rheumatoid arthritis or other connective tissue diseases. In both cases, the infiltration of lacrimal and salivary glands by activated T-cells causes acinar and ductular cell death and subsequent expression of autoantigens at the surface of epithelial cells. However, lacrimal gland infiltration may be also caused by other immune driven disorders including sarcoidosis, lymphoma, graft vs host disease and human immunodeficiency virus (HIV) infection, which should be taken into account during the diagnostic process.

Simple tests for the diagnosis of KCS are Schirmer's test without local anaesthesia (Schirmer I, for measuring the basal secretion rate of the lachrymal gland), calculation of the tear break-up time and slit lamp examination after fluorescein and/or Rose Bengal staining. In addition, corneal examination with the slit lamp may show punctate keratopathy (figure 2) or even filaments.

Schirmer test requires a <10 mm wetting of the paper after 5 minutes for the diagnosis of dry eye. As illustrated in figure 1, paper strips have to be placed in the lower eyelid pouch. The break-up time measures the time the tears break up in the eye by instilling fluorescein into the patient's tear film. The time elapsed between the last blink and the appearance of the first dry spot in the tear film should not be under 10 seconds. The fluorescein and/or Rose Bengal staining detect damages of conjunctival epithelium and cornea.

As regards the diagnosis of Sjögren syndrome, clinical classification criteria have been developed over time. Recently, European–American consensus criteria have been recently developed for the classification of primary Sjögren's syndrome (Shiboski et al, 2017*).

Figure 1 Schirmer's test. Patient consent obtained.

Figure 2 Punctate erosive keratopathy (yellow coloured spots stained with fluorescein).

Treatments for dry eyes consist of topical lubricants, which represent the first line topic approach, and immunomodulating agents, such as cyclosporine A eye drops. As preservatives in eye drops can be toxic to the cornea, the artificial tear substitutes should be preservative free. Omega-3 essential fatty acids have shown anti-inflammatory properties and also improve the quality and quantity of ocular film. Secretagogues can also be taken into account in severe cases, while systemic disease-modifying anti-rheumatic drugs (DMARDs) are reserved for patients with Sjögren syndrome ad extraglandular involvement. Another treatment option is the use of permanent lachrymal plugs (figure 3), which should be inserted intracanalicularly with the aim of stopping

tear fluid drainage. Patients should also be told about simple therapeutic measures, such as using sunglasses and room humidifiers, quitting smoking, and avoiding dry environments.

Figure 3 Intracanalicular implant with a lachrymal plug.

It is known that lachrymal gland functions return to normal in patients with secondary Sjögren's syndrome when the disease remits, so systemic application of immunosuppressive drugs should be considered.

3.1.2 Keratopathy

Corneal disease can be an isolated complication, but it is most commonly associated with KCS or scleritis and may include keratitis, sclerosing keratitis and paracentral or peripheral ulcerative keratitis (figure 4). The origin of this sterile keratitis is an immune complex-mediated vasculitis of the limbal area and it is marked by an inflammatory corneal cell infiltrate that may result in corneal scarring, ulceration, perforation or melting. Patients with keratitis mostly complain of red eye, pain, tearing and blurred vision. The diagnosis is made by slit lamp examination.

In the context of dry eye disease, filamentary keratitis owing to the accumulation of tear film debris or mucus clumping causes eye pain and foreign body sensation. Stromal or sclerosing keratitis are possible complications of anterior scleritis, while interstitial keratitis, involving the corneal stroma without epithelial damage, is associated with Cogan syndrome after having ruled out syphilis, Lyme disease and Epstein Barr virus infection.

Peripheral ulcerative keratitis in patients with rheumatoid arthritis is a rare but classical finding in the rheumatologic context. It is characterised by a progressive thinning of the peripheral cornea due to immune complex deposition and complement activation, followed by activation of collagenases and proteases which in turn leads to keratolysis. This condition may be clinically quiescent with gradual reduction of vision or rarely present with painful eye, severe inflammation up to corneal perforation. Ulcerative keratitis is often independent of systemic disease activity. Because ulcerative keratitis is a sign of active systemic vasculitis and a higher death rate, immunosuppressive therapy will be required to preserve life and vision. In particular, the management is based on topical glucocorticoids; however, in case of perforation, intravenous glucocorticoids

followed by high dose oral glucocorticoids should be administered. In addition to steroids, DMARDs have to be employed as antiproliferative and steroid-sparing agents, while pulsed intravenous cyclophosphamide should be considered in patients with severely active necrotizing forms. More recently, biological therapies have been used, but randomised controlled trials are lacking. In any case, corticosteroids and immunosuppressive drugs should be introduced only after having ruled out an underlying infective cause of corneal ulceration and any secondary infection.

Despite the above-mentioned aggressive medical treatment, surgical intervention will often be required. Surgical options mostly include penetrating keratoplasty or the application of tissue adhesives.

Figure 4 *Peripheral corneal ulceration in rheumatoid arthritis.*

For other than ulcerative keratitis, treatment options consist of local treatments, especially topical lubricants and cyclosporine A eye drops. Because of their antiproliferative character, care must be taken when steroids are used locally. More specific treatments can be taken into account in relation to the systemic disease causing corneal involvement.

3.1.3 Episcleritis and Scleritis

Inflammation of the sclera is a common eye manifestation of the various rheumatic disorders (especially systemic lupus erythematosus (SLE), systemic scleroderma, Wegener's granulomatosis, Behçet's disease and panarteritis nodosa, sarcoidosis, relapsing polychondritis, inflammatory bowel diseases, rheumatoid arthritis and more rarely, the spondyloarthropathies) and includes a spectrum that ranges from harmless simple episcleritis to painful, sight-threatening, destructive necrotising scleritis.

Episcleritis (figure 5A) is a relatively common condition, found especially among young women and often characterized by a self-limiting course. Although episcleritis can be seen in patients with rheumatoid arthritis

and other rheumatologic entities, it is generally a benign recurrent inflammation of the tissue that lies between the conjunctiva and the sclera.

In scleritis the inflammatory process can affect the anterior and/or the posterior part of the sclera, it can be confused with severe conjunctivitis because of the bright red appearance of the eye due to engorged scleral vessels (figure 5B) and may spread to the adjacent tissues, causing ocular complications such as uveitis, keratitis, glaucoma, cataract, optic neuritis, macular oedema, serous retinal detachment or perforation of the globe.

The importance of correctly diagnosing and distinguishing between scleritis and episcleritis is based on the potential ocular and systemic complications associated with scleritis. Indeed, as well as extremely painful, it is a potentially blinding condition associated with autoimmune conditions in around 40% of cases. According to the location of inflammation, scleritis can be divided into anterior, the most frequent, and posterior.

Anterior scleritis may be diffuse when scleral oedema occupies one or more quadrants of the anterior sclera and nodular when one or more raised areas (nodules) of tender scleral thickening are observed. Then, scleritis is distinguished in non-necrotising and necrotising, the latter being the most severe type. Noteworthy, it is particularly important to recognise necrotising scleritis, since it is often associated with ocular complications and a poor prognosis. From a clinical point of view, the eye is extremely painful with radiation to the forehead and temporal region, the ocular globe is tender, while visual loss, discharge and photophobia are generally lacking. The eye is almost always red, but seldom appears white. During inactive phases a bluish/black hue of the sclera can be observed as the result of a scleral thinning owing to previous active scleritis. Acute scleritis can complicate with anterior uveitis, stromal or sclerosing keratitis, globe perforation, glaucoma and even astigmatism as a consequence of the scleral thinning that causes a change in the shape of the eye globe.

Posterior scleritis is less common, but equally sight-threatening. It is associated with systemic autoimmune conditions, especially rheumatoid arthritis and vasculitides, in about 1 out of 3 patients. Also in this case symptoms are characterized by mild-to-severe eye pain, possibly referred to brow or jaw ; in addition, a visual loss and a hypermetropic shift are often recorded as well as lid oedema, proptosis, lid retraction, diplopia. At ophthalmologic examination shallow anterior chamber, choroidal folds, annular choroidal detachment, exudative retinal detachments, macular oedema and optic disc oedema may be observed. The measurement of scleral thickening with B-scan ultrasonography may assist the diagnosis (Murray et al, 2016*).

Taking into account the different nature and prognosis of scleritis and episcleritis, distinguishing between the two ocular entities is essential. Apart from the pain, that is much less severe in episcleritis, the instillation of topical phenylephrine 2.5% brings about blanching of the more superficial vessels of episcleritis, but not of the deeper scleral vessels of scleritis, thus allowing an easy and practical differential diagnosis.

In patients with associated vasculitic systemic disease, the appearance of scleritis indicates a generalisation of the vasculitis, which may have potentially fatal systemic complications. Therefore, only early diagnosis and adequate aggressive treatment can preserve ocular functions and the patient's life.

Figure 5 (A) Episcleritis with engorged episcleral vessels in systemic lupus erythematosus. (B) Scleritis in a patient with rheumatoid arthritis; the inflamed vessels give the eye a bright red appearance.

When required, the initial treatment of episcleritis should be focused on administering ocular lubricants and non-steroidal anti-inflammatory drugs (NSAIDs), at first topically and, then, systemically. In patients who do not respond to these drugs, glucocorticoids or even immunosuppressant agents should be given.

In patients with scleritis, routine treatment with topical non-steroidal or steroidal anti-inflammatory drugs alone is insufficient. However, in many cases systemic NSAIDs are efficacious, in particular flurbiprofen (Agrawal et al, 2016*); if not, short-term treatment with systemic glucocorticoids is recommended. When treatment fails or if only high-dose systemic steroidal anti-inflammatory drugs are efficacious in controlling the scleral disease, immunosuppressive drugs should be added or substituted. In particular, methotrexate, mycophenolate mofetil or azathioprine should be employed. If this is not sufficient to achieve remission, an anti-TNF α biologic agent or the anti-CD20 rituximab may be administered as well. In particular, according to the expert panel recommendations for the use of anti-TNF agents in patients with ocular inflammatory involvement, infliximab may be considered as second-line corticosteroid-sparing therapy in subjects with chronic and severe scleritis (Levy-Clarke et al, 2014*). In patients with scleritis related to granulomatosis with polyangiitis, infliximab may induce different degree of response and rituximab has showed to be noninferior to cyclophosphamide. Conversely, etanercept seems to be not effective in scleritis and cases of paradoxical anterior scleritis have even been reported after the start of etanercept.

In the specific context of patients with posterior or necrotising scleritis, intravenous corticosteroids should be urgently started as rescue therapy, followed by oral corticosteroid in addition to a DMARD or a biological agent.

3.1.4 Uveitis

Uveitis, an inflammation of iris and ciliary body anteriorly and the choroid posteriorly, is subdefined as anterior, intermediate or posterior based upon the location of inflammation relative to the equator of the eye. However, adjacent structures are often involved including the cornea, sclera, retina and the optic nerve.

Then, uveitis may be described as *sudden* or *insidious* according to how ocular inflammation starts; in addition, uveitis may be *limited* when lasts for up to 3 months or *persistent* when lasts for more than 3 months. On this basis, uveitis is *acute* when characterized by a sudden onset and a limited duration. Conversely, the term *chronic* should be limited to persistent uveitis characterized by a relapse within 3 months after the discontinuation of therapy, while the term *recurrent* indicates uveitis characterized by episodes separated by periods of inactivity in patients with no treatment for uveitis (Jabs et al, 2005*).

Overall 30%-40% of uveitis is associated with a systemic disease. In particular, two types of uveitis are commonly found in rheumatic disorders: uveitis anterior and uveitis posterior. The course of inflammation is mostly a chronic relapsing one with an acute onset.

3.1.4.1 Anterior segment changes

Anterior uveitis is an inflammation which is limited to the anterior chamber and can involve the iris and the ciliary body (iritis, iridocyclitis, anterior cyclitis). Anterior uveitis comprises more than 90% of cases. In differential diagnosis physicians should rule out infectious agents including cytomegalovirus, herpes simplex virus, varicella zoster virus, Treponema pallidum, Mycobacterium tuberculosis, Borrelia burgdorferi (Lyme disease). Among non-infectious diseases, anterior uveitis may be caused by local or systemic disorders. The former include trauma and Fuchs's uveitis, an idiopathic condition characterized by modification of the iris colouring, predisposition to cataract and glaucoma, and keratic precipitates on the posterior surface of the cornea. Among systemic diseases the most frequent conditions causing anterior uveitis are: HLA-B27 associated spondyloarthritis, juvenile idiopathic arthritis, multiple sclerosis, Behçet's disease, sarcoidosis, and tubulointerstitial nephritis. Of note, up to one-third of patients with anterior uveitis have ankylosing spondylitis and 50% of patients with anterior uveitis are likely to be HLA-B27 positive in the Western world (Murray et al, 2016*).

Patients with anterior uveitis often have redness, periorbital pain, photophobia and blurred vision. Slit lamp examination shows conjunctival injection, ciliary flush in the perilimbal area, cells and flare in the anterior chamber and fine keratic precipitates (figure 6), which confirm the diagnosis. Keratic precipitates cells (Figure 6) and flare in the anterior chamber and posterior synechiae are characteristic signs of anterior uveitis. Keratic precipitates are inflammatory cellular deposits on the inner corneal endothelium, varying in shape and distribution according to the specific type.

The number of cells in the anterior chamber at the slit lamp correlate with inflammation and this can be graded using a validated scoring system that describes inflammation ranging from 0 (less than 1 cell in 1 mm slit beam) to 4+ (more than 50 cells). Cells may precipitate to the bottom of the anterior chamber forming a white sediment defined hypopyon, more frequent in HLA-B27 associated uveitis and in Behçet's disease. Albumin passed into the aqueous humour organice in the so-called flares, which create opalescence. The severity of inflammation also correlate with flares and are graded according to the intensity of opalescence from 0 to 4+, as detailed in table 1.

Table 1 shows the gradings describing the intensity of inflammation in anterior uveitis as identified according to the density of cells visible in 1 mm slit beam (A) and to the opalescence induced by flares (B). The table is adapted from the Standardization of Uveitis Working Group (Jabs et al, 2005*)

A – Grading for Anterior Chamber Cells	
Grade	Number of Cells in 1 mm slit beam
0	<1
0.5+	1-5
1+	6-15
2+	16-25
3+	26-50
4+	>50
B – Grading for Anterior Chamber Flare	
Grade	Description
0	None
1+	Faint
2+	Moderate (iris and lens details clear)
3+	Marked (iris and lens details hazy)
4+	Intense (fibrin or plastic aqueous)

Figure 6 Acute anterior uveitis; note the keratic precipitates.

Figure 7 Posterior synechia.

Common complications due to intraocular inflammation include posterior synechiae (Figure 8) secondary glaucoma, secondary cataract formation and development of macular oedema (figure 7).

Posterior synechiae are pathologic adhesions between iris and anterior lens capsule capable of changing the pupil into shape irregular forms.

Intraocular pressure may rise for many reasons, especially as a result of corticosteroid treatment and because of the presence of synechiae inducing a complete adhesion of iris on anterior lens capsule, in turn resulting in a decreased flow of aqueous humour through the pupil. Of note, the standardization of uveitis nomenclature working group distinguishes between elevated intraocular pressure, defined as an increase of pressure above

the normal range, and glaucoma, term reserved to those situation in which a visual field loss or a disk damage are observed (Jabs et al, 2005*).

Cystoid macular oedema (CMO) is one of the major causes of vision impairment related to uveitis. Although CMO complicates more frequently intermediate, pan- and posterior uveitis, it is also a relatively uncommon complication of anterior uveitis. The visual acuity is reduced by the accumulation of fluid in the macular area of the retina, which is responsible for central vision. CMO is assessed with fluorescein angiography or optical coherence tomography (OCT) and is generally treated with intraocular injections of the corticosteroids (Fabiani et al, 2017a*).

Figure 8 Cystoid macular oedema in fluorescein angiography.

During an acute inflammatory attack, local treatment should consist of eye drops or ointments containing glucocorticoids. Application frequency depends on the severity of the inflammation. For severe anterior uveitis—for example, if a fibrinous reaction is present, subconjunctival steroid injections may be helpful. In contrast, topical steroids are not effective for macular oedema. For this condition steroids and acetazolamide given systemically are useful. In addition it is necessary to apply sympathomimetics or parasympatholytics locally both to prevent posterior synechiae (figure 8) and to relieve ocular pain.

If local treatment is insufficient, systemic treatment with first-line glucocorticoids and second-line immunosuppressant agents should be discussed. A small number of patients fail to respond to all these treatments and anti-TNF α biologics infliximab or adalimumab should be taken into account (Levy-Clarke et al, 2014*).

3.1.4.2 Intermediate uveitis and pars planitis

The term intermediate uveitis should be used when the vitreous is the site of inflammation; the presence of peripheral vascular sheathing and CMO should not change the classification. The term pars planitis should be used for the subset of idiopathic intermediate uveitis where there is snowbank or snowball formation occurring in the absence infectious or systemic diseases. Consequently, in the rheumatologic context the term pars planitis does not play a part. Conversely, an intermediate uveitis may be found as an expression of sarcoidosis and multiple sclerosis or in the context of syphilis or Lyme disease, but an isolated vitreous inflammation is not characteristic of rheumatic disease.

3.1.4.3 Posterior segment changes

Involvement of the posterior part of the eye, so-called posterior uveitis, includes the retina and the choroid as primary sites of inflammation, while the posterior vitreous humour, optic nerve head and retinal vessels may be secondarily affected (Jabs et al, 2005*). If the inflammation starts in the choroid and then affects the retina, it is called chorioretinitis. If the inflammation begins in the retina and secondarily affects the choroid, it is called retinochoroiditis. Both these manifestations lead to retinal, optic nerve and macular oedema. Posterior uveitis accounts for 15% to 22% of all uveitides and is responsible for about 10% of blindness in western world mostly due to CMO. Although it can affect all age groups, the highest prevalence is observed within the fourth and the fifth decades of life (Rothova et al, 1996*).

Posterior uveitis may be supported by infectious agents such as in toxoplasmosis, cytomegalovirus infections, syphilis, Bartonella (cat-scratch disease) and tuberculosis but also by systemic immune disorders including connective tissue diseases, Behçet's disease, Vogt-Koyanagi-Harada disease and sarcoidosis. However, several ocular-specific affections should be taken in mind as the white dot syndrome, multifocal choroiditis, and birdshot choroidopathy. Diagnosis is based on a careful evaluation of medical history, travel history, slit lamp examination, and ophthalmoscopy. Patients usually do not complain at the beginning of posterior segment inflammation or if the involvement is located in the peripheral retinal areas. Later they may see 'floaters' due to vitreous involvement and, especially when the inflammation is located on the posterior pole, may experience blurred vision up to severe visual loss. In addition to decreased sight, symptoms include deep pain, hyperaemia, photophobia, metamorphopsia, and scotomas. Among instrumental tools, fluorescein angiography, indocyanine green angiography, and ultrasonography may be useful for diagnosis. In addition, OCT may be helpful in detecting and monitoring CMO, epiretinal membranes, choroidal membranes, and macular holes. Fluorescein angiography may confirm the inflammatory activity and identifies neovascularization, capillary non-perfusion areas, and vascular staining in cases of retinal vasculitis. Ultrasonography is a very useful tool, especially when the media is hazy and in cases with cataract or vitreous haemorrhage.

Complications include secondary cataract formation, secondary glaucoma and, as mentioned above, retinal detachment, phthisis of the eye, optic disc atrophy and visual loss that may lead to blindness.

Another severe inflammatory condition of the posterior segment is retinal vasculitis. Typical for this condition are dilatation and engorgement of retinal vessels, cotton wool spots (ischaemic infarcts of the retinal ganglion cell layer) (figure 9), perivascular sheathing with inflammatory whitish yellow exudates and retinal haemorrhages (figures 10–12). Especially in the beginning, at ophthalmoscopy these conditions look like an early hypertensive retinopathy. In cases of occlusive retinal vasculitis, the funduscopy may show occluded, so-called 'silver wired', vessels (figure 13), chorioretinal scars, alterations of retinal pigment epithelium, and retinal and also optic nerve atrophy. In addition, occlusive retinal vasculitis causes tissue hypoxia, which stimulates the growth of new vessels at the optic disc or elsewhere in the retinal layer (Zierhut et al, 2005*). These neovascularisations (figure 14) can rupture and bleed, leading to organisation with membrane formation, causing retinal holes and subsequent retinal detachment.

Figure 9 Multiple cotton wool spots in systemic lupus erythematosus retinopathy.

Figure 14 Retinal and optic disc neovascularisations.

As retinal vasculitis indicates systemic activity of the underlying disease and, as a consequence, a bad prognosis, treatment should be started urgently. Since local treatment is ineffective for retinal involvement, systemic application of glucocorticoids or immunosuppressant agents is required (Perez et al, 2004*). Recent evidences strongly suggest TNF α inhibition as effective therapy for retinal vasculitis, especially in patients with Behçet's disease (Calvo-Río et al, 2014*; Sharma et al, 2015*). In this regard, the American Uveitis Society recommendations claim that infliximab and adalimumab can be considered as first-line immunomodulatory agents in patients with Behçet's disease eye manifestations (Levy-Clarke et al, 2014*). According to data from a Spanish registry enrolling 124 patients with Behçet's disease, the number of patients with retinal vasculitis significantly decreased from 89 (143 eyes) to 8 (13 eyes) at 1-year follow-up after the start of infliximab or adalimumab (Calvo-Río et al, 2014*). Similarly, Vallet et al found an improvement of retinal vasculitis in 46/49 (93.9%) patients with Behçet's disease even though retinal vasculitis was negatively associated with complete response in both univariate and multivariate analysis (Vallet et al, 2015*). Adalimumab administered to 40 Behçet's disease patients with ocular involvement proved to induce a significant reduction of retinal vasculitis already at 3-month follow-up and a further significant decrease at 12-month evaluation. Notably, the concomitant use of DMARDs did not affect the overall response of retinal vasculitis; similarly, no differences existed between patients undergoing adalimumab as first line biologic agent and those previously administered with other biologics (Fabiani et al, 2017b*).

The anti-CD20 rituximab has also been described as a therapeutic opportunity in patients with resistant retinal vasculitis associated to Behçet's disease, systemic lupus erythematosus and granulomatosis with polyangiitis (Hickman et al, 2010*; Najem et al, 2015*; Davatchi et al, 2010*).

Based on retrospective studies, also IL-1 inhibition has revealed good clinical results on retinal vasculitis in terms of prompt and sustained response (Gül et al, 2012*; Fabiani et al, 2017c*).

A very recent work has also highlighted the possibility to use intraocular dexamethasone implants to control recalcitrant retinal vasculitis (Fabiani et al, 2017a*).

3.1.4.4 Panuveitis

The term panuveitis should be reserved for those situations in which inflammation has no predominant, but the inflammatory process is localized in the anterior chamber, vitreous, and retina and/or choroid (Jabs et al, 2005*). As for other subtypes of uveitis, panuveitis may be induced by infectious agents or systemic inflammatory diseases, especially Behçet's disease, Vogt-Koyanagi-Harada disease and sarcoidosis. Clinical manifestations overlap with those described for posterior, intermediate and anterior uveitis and diagnosis is equally based on clinical history, slit lamp examination, ophthalmoscopy, evaluation of intraocular pressure to early identify intraocular hypertension or glaucoma. OCT can help in the early identification of CMO and cystoid macular oedema and fluorescein angiography may find retinal vasculitis, neovascularization, and capillary non-perfusion areas.

3.1.4 Systemic treatment for uveitis

Patients with anterior acute uveitis often respond well to topical corticosteroids and cycloplegic and/or mydriatic agents. Patients with anterior chronic uveitis, intermediate uveitis, posterior uveitis, or panuveitis, often require a more aggressive therapy with tapering high-dose systemic steroids (40 to 80 mg daily of prednisone or equivalent). In severe cases, parenteral steroids should be taken into account. DMARDs, especially azathioprine, methotrexate, mycophenolate, and cyclosporine, should be added in resistant cases or as steroid-sparing agents. However, multiresistant patients are not rare. In these cases biologic agents should be added to improve patients' quality of life and avoid sight-threatening complications. Among biologic agents, TNF α inhibitors take advantage of the wider scientific literature reporting retrospective and prospective trials. According to the recommendations of the American Uveitis Society (Levy-Clarke et al, 2013*), infliximab or adalimumab represent the second-line agents after methotrexate to treat uveitis in patients with juvenile idiopathic arthritis. For patients with Behçet's disease, infliximab or adalimumab were recommended as first- or second-line corticosteroid-sparing agents with high- and moderate-quality evidence, respectively. In the context of spondyloarthritis, infliximab or adalimumab were strongly recommended as corticosteroid-sparing agents, but were only discretionary recommended as adjunctive therapy for sight-threatening uveitis. Discretionary recommendations were made also for the use of infliximab or adalimumab for uveitis in the context of sarcoidosis.

Looking at literature data, infliximab has shown good clinical results in patients with Behçet's Disease, juvenile idiopathic arthritis, sarcoidosis, spondyloarthritis, and Crohn's disease when used at a dose ranging from 3 mg/kg every 8 weeks to 10 mg/kg every 4 weeks. A prospective study on 63 Japanese patients with Behçet's disease (the analysis of efficacy was performed on 50 patients) claimed that at 1-year follow-up infliximab induced an improvement of uveoretinitis in 69% of cases, a slight improvement in 23%, while 8% of patients unchanged (Okada et al, 2012*). In another study on 23 patients with uveitis due to different non-infectious aetiologies, infliximab brought about clinical response in 78% of cases already at 10-week evaluation (Suhler et al, 2009*).

Regarding adalimumab, a prospective study on 31 patients with multiple underlying systemic conditions, response was recorded in 68% of patients at 10-week visit and in 39% at 50-week evaluation (Suhler et al, 2013*). In the VISUAL I randomized placebo-controlled study on 217 patients with non-infectious uveitis, the risk of treatment failure was significantly reduced in the adalimumab arm than patients undergoing placebo, as the median time to treatment failure was 24 weeks for patients undergoing adalimumab and 13 weeks in the placebo group (Jaffe et al, 2016*). In the Visual II study on 229 patients with inactive disease owing to prednisone treatment, patients were randomized to adalimumab or placebo with a mandatory prednisone taper from week 2. Treatment failure was identified in 55% of patients in the placebo group and 39% of patients in the adalimumab group. Time to treatment failure was significantly higher among patients undergoing adalimumab compared with the placebo group (Nguyen et al, 2016*). Adalimumab has been recently tested in 40 patients with Behçet's disease suffering from multirefractory uveitis. The study highlighted a significant decrease in the number of ocular flares during a 12-months study period compared to the 12 months preceding the start of adalimumab, along with a significant improvement of CMO at OCT and of best corrected visual acuity (Fabiani et al, 2017b*).

Among other TNF α inhibitors, golimumab has proved effectiveness in retrospective studies on patients with ankylosing spondylitis, juvenile idiopathic arthritis, Behçet's disease (Yazgan et al, 2016*; Calvo-Río et al, 2016*; Miserocchi et al, 2014*; Vitale et al, 2017*). Conversely, the use of etanercept in patients with uveitis is controversial, as it seems associated with paradoxical uveitis after TNF α inhibition much more than other TNF antagonists (Lim et al, 2007*).

As for other cytokine blockers, current research efforts are directed toward interleukine(IL)-6 and IL-1 inhibition. The monoclonal IL-6 receptor antibody tocilizumab given at the dosage of 8 mg/Kg every 4 weeks has proved to be a successful therapeutic option in patients with uveitis due to various illnesses and previously unresponding to conventional therapy and anti-TNF α agents (Deuter et al, 2017*; Calvo-Río et al, 2017*; Mesquida et al, 2017*). A recent study on 12 patients with various diseases, tocilizumab allowed a significant improvement of central macular thickness and visual acuity at 12- and 24-month follow-up. Tocilizumab was withdrawn in 5 patients because of persistent uveitis remission, but macular oedema relapsed in all cases within 3 months.

Rechallenge of tocilizumab induced a recovery of efficacy (Mesquida et al, 2017*). Another study on 25 patients with juvenile idiopathic arthritis proved the rapid improvement to tocilizumab, with reduction in anterior chamber cell number in 79.2% of patients at 6-month visit and 88.2% at 1-year follow-up. In addition, central macular thickness and visual acuity showed significant improvement at 6-month examination (Calvo-Río et al, 2017*). Of note, 4 patients with juvenile idiopathic arthritis have been recently described as showing a good clinical response to tocilizumab administered intravenously, but experiencing uveitic relapses soon after switching to subcutaneous tocilizumab. On this basis, the Authors speculated that ocular disease may be more readily controlled with intravenous injections owing to the higher blood levels achieved (Quesada-Masachs et al, 2017*).

Gevokizumab has been the first IL-1 antagonist to demonstrate efficacy in severe resistant uveitis in an open-labelled pilot study (Gül A et al, 2012*). The results were later confirmed by an exploratory phase 2 open-label randomized multicentre study (Tugal-Tutkun et al, 2017*). However, although a preserved visual acuity and a less severe ocular inflammation were reported in patients undergoing gevokizumab, gevokizumab has failed to meet the primary endpoint represented by the time to the first acute ocular exacerbation in a recent phase 3 randomised placebo controlled trial. IL-1 inhibition with anakinra and canakinumab for the treatment of uveitis in patients with Behçet's disease has been described in numerous case report and case series over the last decade (Vitale et al, 2016*). A recent retrospective study on 19 patients with Behçet's disease and inflammatory ocular involvement treated with anakinra at the dosage of 100 mg/day or canakinumab at different dosages described a significant reduction of ocular flares from 200 episodes/100 patients/year during the 12 months preceding the start of IL-1 inhibition to 48.87 episodes/100 patients/year during the first 12 months of treatment. In addition, a significant steroid sparing effect and a reduction in retinal vasculitis at fluorescein angiography were observed. Corticosteroid use and the line of biologic treatment did not condition the response (Fabiani et al, 2017c).

Among other biologic agents, abatacept and rituximab have shown a therapeutic role in uveitis, especially among patients with juvenile idiopathic arthritis (Birolo et al, 2016*; Miserocchi et al, 2016*), while IL-17 inhibitors have failed to reach primary efficacy endpoints in three different studies. An interdisciplinary panel consensus on the management of uveitis in juvenile idiopathic arthritis have recently proposed different levels of treatment as a stepwise therapeutic algorithm starting from the use of topical corticosteroids (level I), followed by methotrexate (level 2), adalimumab (level III), infliximab (level IV) and other rescue treatments represented by abatacept, tocilizumab, golimumab or rituximab (level V) (Bou et al, 2015*).

As recommended by a recent expert committee (Wakefield et al, 2017*), before starting any long-term systemic immunosuppressive or biologic therapy, patients should be evaluated to prevent or minimize therapy and disease-related complications. In particular liver or sexually transmitted infections, dental diseases, human papilloma virus infection, and a history of or exposure to tuberculosis should be ruled out. Moreover, bleeding

disorders and thrombosis should be investigated as well as neoplastic diseases and renal, liver, and endocrine disorders. A baseline bone density and fracture risk assessment should be reserved to patients undergoing high-dose and prolonged systemic corticosteroids, looking at adequate treatment when required. Immunization status (HBV, Varicella Zoster Virus, pneumococcus) should also be considered and special attention should be given to children in terms of drug dosages, immunization and long-term effects. Young women should be informed about the need for planning pregnancy and lactation, while elders should be carefully evaluated for co-morbidities, poly-pharmacy and drug interactions.

Finally, it is necessary to keep in mind that ocular surgery—for example, laser coagulation, vitrectomy, cataract extraction, should be carried out only if anti-inflammatory therapy has already been started because of the otherwise high risk of relapse. For retinal hypoperfusion and secondary neovascularisations, laser coagulation may be helpful. Laser coagulation should be performed only if the patient is receiving anti-inflammatory therapy.

3.1.5 Side effects of drugs used to treat rheumatic diseases

The most significant side effects of the drugs used to treat rheumatic diseases are the maculopathy associated with antimalarial agents, and cataracts and glaucoma associated with glucocorticoid use.

3.1.5.1 Antimalarial drugs

The incidence of hydroxychloroquine retinopathy is low. A review of more than 1200 hydroxychloroquine prescriptions filled in a Kaiser Permanente Medical Care Program found only one case of definitive retinopathy (0.08%) and a few cases of indeterminate but probable toxicity (0.4%). The condition is closely related to the daily drug dose and duration of treatment. Risk factors for developing retinopathy include doses of chloroquine >3 mg/kg daily and doses of hydroxychloroquine >6.5 mg/kg daily, doses of hydroxychloroquine >400 mg/day and cumulative doses >500 g.

In 2000, the American Academy of Ophthalmology issued recommendations on screening for chloroquine and hydroxychloroquine toxicity. They suggested that all patients starting either chloroquine or hydroxychloroquine treatment should have a full dilated eye baseline examination within the first year and should then receive an annual follow-up, especially patients at high risk (Marmor et al, 2002*).

3.1.5.2 Tumour necrosis factor α antagonists

Treatment with TNF α blockers will often be started in inflammatory diseases resistant to conventional immunosuppressive agents; however, paradoxically ocular inflammation is a reported adverse event following the use of etanercept. To date, many cases of inflammatory eye disease (uveitis, scleritis, orbital myositis) have been associated with TNF inhibitors, especially etanercept (Lim et al, 2007*).

3.2 Autoimmune diseases (Patel and Lundy, 2002*)

3.2.1 Arthritides

3.2.1.1 Rheumatoid arthritis

Ocular involvement in rheumatoid arthritis is common—found in about 25–30% of patients. KCS can be detected in 15–25% of patients with rheumatoid arthritis, making it the most common manifestation in this disease. Interestingly, the severity of dry eye is independent of rheumatoid arthritis activity.

Scleritis or episcleritis occurs with a frequency of 4–10% and in scleritis, rheumatoid arthritis is the most common cause of this manifestation, accounting for about 18–33% of cases. Corneal disease in patients with rheumatoid arthritis can be an isolated complication but is most commonly associated with KCS or a form of anterior scleritis. Other rare manifestations are choroiditis, retinal vasculitis, idiopathic retinal haemorrhage, retinal detachment and macular oedema. Special attention should be given to peripheral ulcerative keratitis, as it is both a sight-threatening complication and a sign of active systemic vasculitis requiring resolute treatment.

3.2.1.2 Spondyloarthropathies

Among the seronegative spondyloarthropathies, the most frequent ocular manifestation is acute anterior, unilateral, relapsing, uveitis. It may occasionally be bilateral. Often anterior uveitis is the first symptom of a previously undiagnosed HLA-B27 associated disease, especially among female subjects. The prognosis of uveitis is usually excellent with topical treatment, and only those with posterior pole involvement with a tendency to chronicity might benefit from systemic anti-inflammatory treatment. Other rare ocular involvement includes KCS, keratitis, scleritis and posterior uveitis (Lyons and Rosenbaum, 1997*).

Ankylosing spondylitis. During the course of their disease, about 25–40% of patients with ankylosing spondylitis develop anterior uveitis, which occurs relatively more often in HLA-B27-positive than in HLA-B27-negative patients. There is a minor correlation between the activity of ankylosing spondylitis and the development of anterior uveitis. In ankylosing spondylitis, in particular, but also in other HLA-B27 associated inflammatory diseases, sulfasalazine is a possible treatment for preventing recurrences and reducing the severity of anterior uveitis.

Reactive arthritis. Conjunctivitis is the most common ocular symptom in reactive arthritis and usually appears within a few weeks of the onset of arthritis or urethritis in about 58% of patients. The second most common ocular symptom is anterior uveitis, occurring in up to 12% of patients. Anterior uveitis is more frequent in patients who are HLA-B27 positive and in those patients who have sacroiliitis. In addition, episcleritis, scleritis, keratitis, retinal oedema and retinal vasculitis have all been reported.

Psoriatic arthritis. Eye involvement in patients with psoriatic arthritis occurs in up to 10% and is described mainly in patients with associated arthritis. In the literature, scaling of the eyelids, conjunctivitis, dry eye syndrome and anterior uveitis have been noted, interestingly twice as often in men as in women.

Enteropathic arthritis. The eye is involved in 4–10% of patients with enteropathic arthritis. Acute anterior uveitis but also episcleritis and marginal keratitis have been most frequently reported. In 1991, Salmon and co-workers reported that patients with additional arthritis or arthralgia had a higher incidence of ocular inflammation than patients without joint involvement.

3.2.2 Connective tissue disease

3.2.2.1 Systemic lupus Erythematosus (SLE)

Ocular manifestations of SLE most often reflect systemic disease and occur in 20% of patients, but independent studies also show the possibility of ocular inflammatory problems preceding diagnosable SLE by more than 5 years. KCS is the most common and is present in 10–25% of cases. Episcleritis and scleritis can be found in about 10% of patients and necrotising scleritis occurs in 23% of inflamed eyes. Other ocular changes of the anterior eye segment include uveitis, interstitial keratitis and a discoid lupus rash over the eyelids, which is often confused with blepharitis.

In the posterior eye segment, the retina and the choroid are frequently involved, second only to KCS, and in 88% of these affected patients active SLE is present. Cotton wool spots (figure 9) and haemorrhages are the most commonly reported retinal findings, but retinal and macular oedema, microaneurysms and occlusive retinal vasculitis have also been noted.

Several reports indicate a role of antiphospholipid antibodies in retinal and choroidal vasculopathy, although their precise role in this process is uncertain. In addition, neuro-ophthalmological manifestations like optic neuritis, ischaemic optic neuropathy, and chiasmal and retrochiasmal problems such as internuclear ophthalmoplegia, have been seen. The possibility of a false diagnosis of multiple sclerosis due to the presence of internuclear ophthalmoplegia and optic neuritis should be kept in mind.

If retinal involvement is present, aggressive treatment is required owing to high morbidity (Soo et al, 2000*).

3.2.2.2 Systemic sclerosis

The main ocular feature in this disease entity is KCS and is seen in about 40–70% of patients with systemic sclerosis. In addition to the inflammatory changes of the lachrymal gland, patients will have fibrotic changes of the eyelids, the conjunctiva and the lachrymal ducts. Episcleritis is present in 5% of patients. Retinal involvement occurs in about 50% of patients and is manifested most often as a mild retinopathy with cotton wool spots and intraretinal haemorrhages.

3.2.2.3 Primary Sjögren's syndrome

Primary Sjögren's syndrome is characterised by an active inflammatory stage followed by a chronic stage. The KCS is probably due to residual lachrymal gland damage from the initial active process. Corneal ulceration and perforation due to KCS is described in patients with Sjögren's syndrome.

In addition to the treatment noted above, oral pilocarpine may improve the symptoms of dry eyes and dry mouth.

3.2.2.4 Dermatomyositis

The hallmark of ocular involvement is the heliotrope rash affecting the eyelids. In addition, episcleritis, scleritis, keratitis, anterior uveitis and retinal vasculitis rarely occur.

3.2.3 Vasculitides

3.2.3.1 Large vessel vasculitis

Giant cell (temporal) arteritis. It is important to note that ocular involvement is not uncommon in the absence of systemic signs and symptoms. Hayreh and co-workers reported that about 50% of their patients had both ocular and extraocular symptoms, while 21.2% presented with ocular involvement only (Hayreh et al, 1998*).

Patients may complain of pain, visual loss, diplopia and amaurosis fugax. The most severe ocular involvement of giant cell (temporal) arteritis is sudden loss of vision from ischaemic optic neuropathy (in 81–94% of these patients) or central retinal artery occlusion. Both manifestations may be irreversible and bilateral. The reported prevalence of vision loss ranges from 15% to 50%.

Diagnosis is confirmed with biopsy of the temporal artery and raised titres of erythrocyte sedimentation rate and C-reactive protein. Biopsy will remain positive for up to 2 weeks after starting glucocorticoid treatment. Immediate treatment with intravenous glucocorticoids is quickly effective and prevents permanent visual loss.

Takayasu's arteritis. Up to 40% of patients with Takayasu's arteritis have microaneurysms and arteriovenous anastomoses due to underlying retinal vasculitis identified by fluorescein angiography. Neovascularisations and consequent vitreous haemorrhage can occur secondary to retinal ischaemia.

3.2.3.2 Medium vessel vasculitis

Polyarteritis nodosa. An ocular manifestation is present in 10–20% of patients with polyarteritis nodosa and includes episcleritis, scleritis (diffuse, nodular or necrotising), peripheral ulcerative keratitis (which may be the initial presenting symptom) and inflammation of the orbital vessels. The last of these may lead to bilateral orbital pseudotumour, resulting in exophthalmos.

Manifestation in the posterior eye segment is frequent in polyarteritis nodosa and choroidal involvement is the most common. Also, direct involvement of the retinal vasculature (arteries) can cause occlusive retinal vasculitis, cotton wool spots and central retinal artery occlusion, whereas vasculitis of the optic nerve vasculature can lead to papilloedema, papillitis and optic nerve atrophy. The described retinal findings may also occur secondary to systemic hypertension or renal disease. In addition, neuro-ophthalmological manifestations can occur and include extraocular muscle palsies, amaurosis fugax, homonymous hemianopia and nystagmus.

When the eye is involved, immediate treatment with systemic glucocorticoids and/or immunosuppressant agents is required.

Kawasaki's disease. Anterior uveitis occurs in up to 66% of patients, mostly in the first week of disease manifestation. Other ocular involvement includes conjunctival hyperaemia, keratitis, papilloedema and rarely, retinal vasculitis.

3.2.3.3 Small vessel vasculitis

Churg–Strauss syndrome. Involvement of the anterior eye segment may present as granulomatous nodules of the conjunctiva and the eyelids, episcleritis and marginal corneal ulcer. Panuveitis, retinal vasculitis with branch retinal artery occlusion and optic disc vasculitis have been described as manifestations in the posterior eye segment. Neuro-ophthalmological involvement may be present as ischaemic optic neuropathy, amaurosis fugax and cranial nerve palsies. In most cases, the intraocular inflammation resolves after systemic glucocorticoid therapy.

Cutaneous leucocytoclastic vasculitis. Ocular involvement is rare. In the literature only a few cases with anterior uveitis, panuveitis, multifocal chorioretinitis and vasculitis have been reported. Treatment with systemic glucocorticoids is sufficient to control the ocular disease in most cases.

Essential cryoglobulinaemic vasculitis. Slit lamp examination may reveal corneal deposits of cryoglobulin. Therapeutic options include superficial keratectomy and excimer laser phototherapeutic keratectomy. In addition, a Purtscher-like retinopathy (retinopathy of the central retina after thoracic trauma with cotton wool spots, exudates, haemorrhages and engorgement of retinal veins), retinal vasculitis and serous retinal detachment have been reported.

Henoch–Schönlein purpura. Manifestations in the eye are rare. Only a few cases have been reported, and they include episcleritis, keratitis and anterior uveitis.

Microscopic polyangiitis. Ocular involvement is rare, but in patients with microscopic polyangiitis eye inflammation may be the first presenting symptom and prompts the patient to seek an appointment with the

ophthalmologist. Most often these presenting symptoms are nodules of the eyelids and of the conjunctiva with central ulceration or peripheral ulcerative keratitis.

Wegener's granulomatosis. Ocular manifestations are seen in 29–52% of patients, 15% of whom have already presented with ocular disease. In principle, Wegener's granulomatosis can affect any ocular or periocular structure, but orbital involvement is most common (50%). As a consequence, secondary changes such as compressive optic neuropathy, exophthalmos and exposure keratopathy may be seen. Other complications, which occur in about 25% of patients, are dacryoadenitis, dacryocystitis and occlusion of the nasolachrymal duct. Owing to inflammation of the lachrymal gland, dry eye syndrome is present in about 50% of patients and episcleritis, scleritis and marginal corneal ulceration may be present in an additional 25%. Patients with scleritis, in particular, demonstrate the necrotising or posterior type, which both have a bad prognosis and require immunosuppressive therapy. Occlusive retinal vasculitis, retinitis, choroiditis and ischaemic optic neuritis have also been described. Neuro-ophthalmological involvement may result in Horner's syndrome, cranial nerve palsy and cavernous sinus thrombosis.

3.3 Autoimmune diseases with secondary vasculitis

3.3.1 Relapsing polychondritis

Ocular manifestations occur in up to 59% of patients with RP, the most common being scleral involvement, which has a frequency of 41%. In these patients all types of scleral inflammation (recurrent episcleritis, necrotising and posterior scleritis) may be seen; anterior diffuse scleritis has most often been reported. Other eye manifestations include anterior uveitis (25%), keratitis (10–15%) and ischaemic fundus changes, such as cotton wool spots, intraretinal haemorrhages, branch or central retinal vein occlusions and ischaemic optic neuropathy (Rucker and Ferguson, 1965*).

3.3.2 Cogan's syndrome

The typical ocular manifestation consists of bilateral non-syphilitic interstitial keratitis with patchy vascularisation of the middle and deep corneal stroma. Other reported manifestations are eyelid oedema, conjunctival injection, scleritis and mild iritis.

3.3.3 Sarcoidosis

Eye involvement occurs in 25–30% of patients with sarcoidosis. In 50% of these patients inflammatory changes of the lachrymal glands are present. Anterior uveitis can be seen in 20–70% of patients with a possible occurrence of iris granulomas. Changes in the posterior eye segment (14–43%) include retinal vasculitis with typical 'candle wax' phenomena of the retinal vessels and often a multifocal choroiditis (white (inflammatory)

spots on the retina) will occur. In about 10–17% of patients with sarcoidosis, intermediate uveitis has been reported in combination with retinal periphlebitis (especially venous sheathing).

3.4 Pseudovasculitides

3.4.1 Angioid streaks

Angioid streaks are a generalized disorder of the Bruch membrane, appearing as bilateral, narrow, irregular lines deep to the retina configured in a radiating fashion from the optic disc. They are mainly seen in Pseudoxanthma elasticum, Paget's disease and Ehlers–Danlos syndrome. However, no systemic disease will be diagnosed in 50% of these patients.

The ruptures in the Bruch membrane results in angioid streaks resembling choriocapillaries. The development of subretinal membranes, with a pronounced impairment of visual function, is possible when the defects reach the macular region. Treatment with photocoagulation is in most cases unsatisfactory.

SUMMARY POINTS - Eye involvement

- Patients with rheumatic disease often have keratoconjunctivitis sicca, keratopathy, episcleritis/scleritis, uveitis anterior or posterior and retinal vasculitis.
- The most severe manifestations affecting visual acuity are uveitis and retinal vasculitis.
- Eye involvement may be the first symptom of rheumatic disease and requires intensive diagnostic and often systemic therapy.
- Biologic agents have really improved the outcome of ocular manifestations in rheumatologic diseases

IN-DEPTH DISCUSSION I

Cardiovascular involvement in Behçet's disease

Vascular involvement is a common complication of Behçet's disease (BD) and affects up to 40% of BD patients. These complications worsen the prognosis of BD. The concept of vasculo-Behçet has been adopted for cases in which vascular complications dominate the clinical features. Vascular manifestations affect particularly young men, during the first years following onset of the disease. Venous involvement outnumbers arterial disease (approximately 85% vs 15%) (1, 2, 3). Treatment is based on corticosteroids and immunosuppressive drugs. The use of anticoagulation in venous thrombosis is still controversial.

Venous involvement

Venous complications are the most frequent vascular complications, affecting 14 to 40% of BD patients. Superficial and deep lower limb thrombosis is the most frequent venous complications but one third of venous thrombosis concern large vessels (such as cerebral venous thrombosis, pulmonary embolism, and inferior or superior vena cava).

Deep vein thrombosis (DVT) of the legs makes up 70 % of all vascular manifestations and is observed as an acute or subacute swelling of the involved extremity (4). Pain usually accompanies swelling while, as a novel observation venous claudication, manifested as difficulty in walking due to venous stasis, can also be seen (5). It is bilateral in 60% of the patients. Popliteal and superficial femoral veins, tributary veins of the calves, common femoral, external iliac and common iliac veins are diseased in decreasing order (6). A post-thrombotic syndrome characterized by stasis dermatitis and leg ulcerations is not unusual in the long term.

Less common forms of venous involvement are superior and inferior vena caval disease, Budd-Chiari syndrome and cerebral venous thrombosis (7). Superior vena caval disease leads to cyanosis and swelling of the face and upper extremities whereas inferior vena caval involvement causes venous collaterals in the abdomen, leg swelling and leg ulcers. The former has a more favourable prognosis. The Budd-Chiari syndrome is rare (1.5-3.2%). It is, however, the most lethal pathology of the venous spectrum causing a one year mortality of approximately 50% (8). Cerebral venous thrombosis accounts for 17-30% of central nervous system involvement and is usually manifested as headache and papilloedema; findings of intracranial hypertension (9, 10). It responds well to pulses of methylprednisolone.

Like all serious manifestations of BS, males have a higher risk of having venous disease compared to women (40% vs 5%) (1, 2, 3, 11). The vascular events usually occur within 5 years of disease onset although venous disease as the initial manifestation of BS is also a possibility (1, 3). Recurrence is common (23% after 2 years and 38% after 5 years in a retrospective study) and coexistence with arterial involvement is frequent (4).

The management of venous disease is controversial. Some groups use routine anticoagulation whereas others utilize immunosuppressives. A combination of the two approaches is also occasionally advised (12) The absence of embolisation, the lack of a consistent coagulation abnormality (13,14) coupled with a tightly

adherent thrombi to the vessel wall suggesting an inflammatory pathology (15) favours the use of immunosuppressives but controlled data are lacking.

Arterial involvement

Although not very frequent (15% of all vascular involvement in BS, range 5-18%) (16), arterial involvement is responsible for most of the serious morbidity and mortality in BS. It is mostly associated with aneurysms and less frequently with occlusions of the major arteries although combinations are also possible (6, 17). Recurrences are observed (18).

One of the main patterns of arterial involvement is aneurysms of the peripheral arteries. They are seen in decreasing order of frequency in the abdominal aorta, pulmonary, femoral, popliteal and carotid arteries (1, 16, and 19).

Fever, fatigue and an increased acute phase response characterize the early stages of these aneurysms. With the exception of those in the abdominal aorta, they usually present as a painful, pulsatile hyperaemic mass. Abdominal aortic aneurysms, on the other hand, cause non-specific findings such as back or flank pain or constipation necessitating a high degree of suspicion (20).

Peripheral arterial aneurysms should be managed surgically since they do not regress spontaneously. Ligation is the preferred approach if the circulation is adequate and graft replacement with synthetic grafts if it is not sufficient (21). Immunosuppressive therapy should be given before surgery especially in cases in which the disease is active (22).

The second important pattern of arterial involvement is the pulmonary arterial aneurysms (PAA). They are observed in around 5% of the patients, are usually seen at an earlier stage than other types of arterial involvement (mean age 31 years compared to 39 years) and are the leading cause of mortality in BS (3, 4). A literature review has shown that 89% of the patients with PAA are males (23). The aneurysms, usually bilateral, develop preferentially in the large and medium sized pulmonary arteries (24). Thrombi within the aneurysms are also common.

PAA usually present with haemoptysis, accompanied by chest pain, cough and dyspnoea in varying degrees. Fever and fatigue may also be seen. Coexisting venous thrombosis is present in 81% of the patients with PAA (25) and intracardiac thrombus formation and arterial disease in other sites may additionally complicate the clinical picture (26).

A plain chest radiograph usually shows round hilar or peripheral opacities (27). Spiral CT scan of the lungs shows the aneurysms and the accompanying thromboses in most of the cases and may also be used in monitoring therapy (28). Parenchymal areas of consolidation probably due to ischemic areas caused by

thrombi in the minor pulmonary arteries may accompany or precede the aneurysms (29). Multi slice CT and MR angiography are other imaging alternatives (30). Technetium-99m-hexamethylpropylene amine oxime lung scintigraphy has also been proposed as a tool (31). Pulmonary angiography should not be performed since it has the risk of causing new aneurysms and thromboses at the puncture site.

The presence of haemoptysis may lead to the misdiagnosis of tuberculosis, a condition endemic in BS prevalent geographies. The abundance of the haemoptysis in pulmonary arterial aneurysms and its characteristic radiological findings differentiate the two conditions. The frequent association with deep venous thrombosis of the legs also causes confusion with thrombo-embolic disease; sometimes leading to unnecessary and dangerous anti-coagulation. The occasional presence of perfusion defects in ventilation perfusion scintigraphies of the lungs adds to the dilemma. The presence of aneurysms in imaging studies and the other manifestations of the syndrome aid in the differential diagnosis (23, 32).

The medical treatment of pulmonary arterial aneurysms is empirical. Three pulses of 1 gr of methylprednisolone followed by 1 mg/kg/day of oral prednisolone and monthly boluses of 1gr of intravenous cyclophosphamide is what we usually prefer. The steroid dose is tapered according to the clinical response and is discontinued in 1 year. The cyclophosphamide intervals are switched to every second month after one year and all therapy is discontinued at the end of 2 years. The whole cycle is repeated in case of a relapse. Anecdotal reports of successful therapy with infliximab have also been reported (33). Surgery is not satisfactory due to the multiple nature of the aneurysms (34).

The prognosis of pulmonary arterial aneurysms has improved in recent years. A one year mortality of 50% was reported 15 years ago (30) that decreased to 15% in 10 years, probably due to earlier diagnosis and treatment (25).

Cardiac involvement

Cardiac complications occur in up to 6% of BD patients. Cardiac abnormalities include pericarditis, endocardial lesions (aortic regurgitation and less often mitral insufficiency), myocardial lesions (myocardial infarction, myocarditis and endomyocardial fibrosis) and intracardiac thrombosis (right ventricle and atrium). Coronary lesions complicated to myocardial infarction are the most severe cardiac complications. The prognosis of cardiac involvement in BD is poor and improves with oral anticoagulation, immunosuppressive therapy, and colchicine (35).

IN-DEPTH DISCUSSION II

Biotherapy in Behçet's disease

BD significantly increases morbidity and mortality. The leading cause of morbidity in BD is eye involvement with the potential threat of visual loss. Male sex, arterial involvement, and the number of flares are associated with mortality in BD (1).

Over the past year substantial advances have been done in the understanding of the genetic and immunology of BD. BD is at the crossroad between autoimmune and autoinflammatory syndromes. The pathogenesis of BD is still unknown, but major determinants of the genetic and immune system abnormalities have been reported recently. Triggering infectious factors are supposed to participate in the outbreak of BD in genetically predisposed patients. Two recent large genome-wide association study (GWAS) conducted in Turkey and Japan reported association between single nucleotide polymorphism (SNP) of interleukin (IL)-10 and IL-23R/IL-12RB2 genes and BD. New insights into the perturbations of T cell homeostasis of BD recently emerged. We have demonstrated the promotion of Th17 responses and the suppression of regulatory T cells (Tregs) that were driven by interleukin (IL)-21 production and that correlates with BD activity. Inflammatory cells within BD inflammatory lesions included mostly neutrophils, Th1 and Th17 cells, and cytotoxic CD8+ and $\gamma\delta$ T cells. Altogether, the recent progresses in the knowledge of BD pathogenesis pave the way for innovative therapy. Therapeutic management of BD depends on the clinical presentation and organ involved (2, 3). Although colchicine, nonsteroidal anti-inflammatory agents and topical treatments are often sufficient for mucocutaneous and joint involvement, more aggressive approach with immunosuppressive agents is warranted for severe manifestations such as posterior uveitis, retinal vasculitis, vascular, neurological and gastrointestinal involvement. However, some patients still have refractory disease, relapse, sight threatening eye disease, or irreversible organ damage. Recent improvements in the understanding of the pathogenic mechanisms have led to the identification of potential targets and future therapies for BD. In contrast to current non-specific immunosuppressive agents mainly used empirically, the emergence of biotherapies provides the possibility of interfering with specific pathogenic pathways. Novel targeted biotherapies might be used in the future for BD.

Biotherapies in BD: new therapeutic options

Proinflammatory cytokines, B- and T-cells play an important role in the pathogenesis of BD (4–7). Therefore, immunomodulatory approaches with biotherapies such as modulation of NF κ B expression, inhibition of TNF α , IL-1 or IL-6 signalling, B- or T-cells depletion has been proposed as therapeutic option for BD. In patients presenting with severe BD disease, more targeted therapies offer the potential advantage of faster delay of action as compared the generally slow response to conventional immunosuppressive drugs.

Interferon α

Since the first report of therapeutic effect in three cases of BD treated by IFN α in 1986, the efficacy of IFN α has been well established, especially in sight-threatening ocular manifestations (8–12). In 2004, Kötter and al

reported in a large literature review that 94% of patients with ocular BD exhibited partial or complete remission within 2 to 4 weeks after onset of IFN α (13). Intermediate to high IFN α dosages (18 to 126 x10⁶ UI/week) were more effective than low-dose regimens (5 to 9 x10⁶UI/week) and led to up to 56% long-term remissions after discontinuation of IFN α . IFN α has dramatically improved the long-term visual prognosis in patients with severe ocular BD (11, 12, and 14). In 53 patients followed during a median of 6 years (range 2–12.6 years), 89% were in remission after 2 years of IFN-alpha therapy and ocular BD was still in remission in 50% of the patients 46 months after cessation of the first IFN course (14). Compared with TNF alpha antagonists, IFN α offers the advantage that even after cessation of treatment a high percentage of patients remain in remission. Currently, the use of TNF α -antagonists is only recommended in patients who are intolerant or with ocular manifestations resistant to IFN α . Regarding the use of infliximab for ocular involvement resistant to IFN α , remission was observed in 18 of 20 patients (15–22). Interferon α is generally administered subcutaneously, with a dose between 3 and 9 million units, most often 3 times weekly. To avoid an antagonistic effect of IFN α which works via NF κ B, corticosteroids (which blocked NF κ B) need to be use at the lowest dose as possible when associated to IFN α (14). Furthermore, an open Turkish trial of AZA plus IFN α in 10 male BD patients with retinal involvement had to be stopped because of additive hematologic toxicities (23). Pain and duration of oral ulcers, number of pustular papules, as well as frequency of genital lesions, erythema nodosum-like lesions and thrombophlebitis are also significantly reduced in patients receiving IFN α compare to those receiving placebo (9). In an open trial including 50 patients treated by IFN α for refractory ocular BD (24), IFN α was effective on ocular manifestation with a response rate of 92%. This treatment was also beneficial for the extraocular manifestations of the disease, i.e. genital ulcerations, arthritis, and skin lesions, although less so for oral aphthous ulcers (24). A case series of 2 male adolescents reports that IFN α is also effective for refractory juvenile BD with CNS involvement (25). Thus, IFN α is not only an alternative treatment for uveitis but also for extra-ocular manifestations of BD. Adverse effects are common, especially the flu-like syndrome that occurs in almost all patients but it is easy to prevent with paracetamol. In addition, depression, asthenia, cytopenia and in a lesser extent, psoriasis and sarcoidosis can be induced or worsened. However, IFN α is the one of the only therapy that allows sustained ocular remission after discontinuation of the treatment.

Thalidomide

Thalidomide is also an immunomodulatory drug by suppressing TNF α -induced NF- κ B activation and ATP-induced IL-1 β secretion (26). Modulating the activity of NF- κ B, thalidomide can up-regulate the expression of downstream genes involved in the pathophysiology of BD. Thalidomide has reported efficacy in treating patients with mucocutaneous lesions refractory to treatment with colchicine. However, teratogenicity, neurotoxicity, and constipation restrict usage of this drug (27, 28).

Inhibition of cytokine signalling

Anti-TNF α

TNF α -antagonists are increasingly used for patients with BD, especially infliximab and in a lesser extent adalimumab (29–32). We find no report with certolizumab in BD but the first case of BD with refractory uveitis treated by golimumab has been recently reported (33). Nevertheless, only 1 randomized, double-blind, placebo-control trial assessed the effect of etanercept on mucocutaneous manifestations and arthritis (34). Among anti-tumor necrosis factor (anti-TNF) agents, infliximab has been used in more than 300 cases, mainly for refractory ocular BD and with 89% of improving patients who were resistant to conventional therapies (15, 19, 31, 35–41). The relapse rate of uveitis and daily corticosteroid doses were significantly lower during infliximab treatment (42) in patients with BD in whom uveitis was resistant to combination therapy with corticosteroids, azathioprine, and cyclosporine (38, 43). In 2004, Giasanti and al reported a case of retinal neovascularization caused by panuveitis in BD that completely regressed 8 months after the first anti-tumor necrosis factor treatment and with six infusions of infliximab (44). Complete remission were observed in 83% and 82% of patients with gastrointestinal and CNS involvement, respectively (18, 45). Rapid onset of action and steroid-sparing effect characterize the efficacy of TNF α -antagonists, mainly reported in patients resistant to conventional therapies (19, 36–38, 40, 46–49). The switching of anti-TNF- α agents after a failure of a first anti-TNF- α agent can be an alternative therapeutic option but the two monoclonal antibodies, infliximab and adalimumab, seem more effective than the soluble antibodies, etanercept notably for uveitis (50, 51). However, repeated long term infusions are warranted to sustain remission (usually at week 0, 2, 4, then at interval 6 to 8 weeks) as TNF α -antagonists are likely suspensive. Other important issue is the use of associated immunosuppressive drug (CsA, AZA or MTX) in association with TNF α -antagonists that could be not only prevent the production of TNF α antibodies but also could be more effective compared to monotherapy (31, 52).

Anti-IL1

IL-1 has been found elevated in sera of patients with BD (53). Anakinra is a recombinant, non-glycosylated human IL1 receptor antagonist and was shown effective in case report of BD patient refractory to conventional treatments (54). More recently, an open-label pilot study show that XOMA 052 (gevokizumab), a recombinant humanised anti-interleukin 1 β antibody, was well tolerated and resulted in a rapid onset and sustained reduction in intraocular inflammation in seven patients with resistant uveitis and retinal vasculitis. Complete regression of intraocular inflammation was achieved in 4-21 days (median 14 days). All patients except one were in remission after 28 days. Moreover, the beneficial effect was observed despite discontinuation of immunosuppressive agents and without the need to increase corticosteroid dosages (55). Canakinumab, a human monoclonal antibody targeted at interleukin-1 beta, has been used successfully in 2 patients with

resistant BD (56, 57). Similarly to switching of anti TNF- α agent, one of the patient with resistant ocular BD including failure of anakinra, responds after to canakinumab (56).

Anti-IL6

The level of IL6 is associated with disease activity according to several studies (58, 59). Tocilizumab, a humanized anti-interleukin 6 receptor antibody, is currently approved only for the treatment of moderately to severely active rheumatoid arthritis refractory to one or more anti-TNF drugs. It may constitute a therapeutic option for refractory Behçet's disease. Three resistant cases of BD with recurrent meningo-encephalitis or uveitis have been successfully treated with tocilizumab (60–62).

Lymphocytes-targeted therapies

Anti-CD20

Rituximab is an anti-CD20 antibody, which depletes B-lymphocytes. Rituximab, given in two 1000-mg courses (15-day interval), was found effective in severe ocular lesions including retinal vasculitis due to Behçet's disease, resistant to prednisolone, azathioprine and etanercept (63,64).

Anti-CD52

The predominant effect of anti-CD52 antibody therapy (alemtuzumab) is T-cell depletion. Alemtuzumab, given in one course of 134 mg, can induce sustained treatment-free remission in BD poorly controlled by conventional therapy (65, 66). Among 18 patients with orogenital ulcerations (100%), ocular involvement (66.7%) and/or neurological involvement (72%), 72% had entered remission and 33% could discontinue their treatment.

Anti-CD25

Daclizumab, a humanized monoclonal antibody against CD25, was not superior to placebo in a randomized, placebo-controlled, double-blind trial including 17 patients with severe ocular BD (67).

Biotherapies in the therapeutic strategy of BD

During last decades, therapeutic strategy in BD becomes more intensive in terms of immunosuppressive use. Although novel biotherapies currently available appear highly effective in uncontrolled studies and with rapid onset of action in different clinical situations, no consensus exists about their use in BD. Refractory manifestations that may warrant biotherapy include severe ocular, CNS, and vascular involvement and some severe or refractory gastrointestinal, joint, and mucocutaneous involvements. In clinical practice, colchicine is the most frequently and widely used drug for oral ulcers, genital ulcers, papulopustular lesions and arthralgias.

Polymyalgia rheumatica and giant cell arteritis

Gouri Koduri, Bhaskar Dasgupta, Charles Masson

A previous version was coauthored by Miguel A. Gonzalez-Gay, Brian Hazleman, Nicolo Pipitone, Carlo Salvarani, Javier Rueda

LEARNING OBJECTIVES

- Describe the epidemiology and the association between polymyalgia rheumatica (PMR) and giant cell arteritis (GCA)
- Describe the mechanisms involved in the pathogenesis of PMR and GCA
- Correctly diagnose PMR and GCA on the basis of their common and less common clinical manifestations. 2012 EULAR - ACR classification criteria, overlap between PMR, GCA and Inflammatory arthritis
- Define the role of laboratory investigations and imaging studies in the diagnosis of PMR and GCA and the role of histology in GCA
- Distinguish PMR from other inflammatory disorders that may present with clinical features mimicking PMR
- Treat patients with PMR and GCA, 2015 EULAR ACR treatment guidelines for PMR

Polymyalgia rheumatica (PMR) is an inflammatory disorder characterised by pain, aching and morning stiffness in the shoulder girdle and often in the pelvic girdle and neck. Giant cell arteritis (GCA), also known as Horton or temporal arteritis, is a vasculitis mainly involving the large and medium arteries, especially the branches of the proximal aorta, including extracranial branches of the external carotid artery such as the temporal arteries (Dejaco et al 2016; Salvarani et al, 2002; Weyand and Goronzy, 2003; Gonzalez-Gay et al, 2006; Salvarani et al, 2008b; Masson, 2012*; Kermani and Warrington, 2013; Weyand and Goronzy, 2014*). Epidemiological studies suggest that PMR and GCA occur together more often than expected by chance alone. Both disorders almost exclusively affect patients aged ≥ 50 years. A systemic inflammatory response and a marked response to glucocorticoid therapy are typical features of PMR and GCA, although in GCA higher doses of glucocorticoids are required. Classically, PMR and GCA generally require treatment for 18 – 24 months. However, over 50% of patients have a chronic relapsing course and may require glucocorticoids for several years.

Overall, neither disease causes excess mortality, but significant morbidity and even increased mortality in some sub groups (such as patients with irreversible sight loss) is seen, mainly resulting from glucocorticoid-related adverse reactions. Principal glucocorticoid side effects—for instance, diabetes, hypertension, hyperlipidaemia and osteoporosis, should be monitored and measures taken to prevent and manage them.

The mainstay of the treatment of GCA is glucocorticoid therapy.

However, three phenotypes should be distinguished: cranial GCA, large vessel GCA and isolated PMR.

Symptoms of cranial GCA may consist of isolated temporal headache without evidence of ischemia.

Complicated GCA is defined by the presence of ischemic lesions involving the optic nerve and disc or retina (ciliary arteries and central retinal artery), which carries a heavy burden of permanent blindness; or involving the aorta and branches of the aortic arch (aortitis, aneurysm, dissection, stenosis and occlusion), or other arteries such as the vertebral or upper-limb arteries. All patients with more than low probability of suspicion for GCA require glucocorticoid treatment and fast track specialist assessment and appropriate intervention should be started on the same day.

1 Classification criteria for PMR

One of the challenges in the diagnosis of PMR is the lack of any diagnostic tests that are specific for this condition. Additionally, several other conditions can mimic this diagnosis or present with polymyalgic symptoms.

Several diagnostic criteria for PMR have been proposed based on retrospective clinical series (Bird *et al.* 1979; Jones and Hazleman, 1981; Chuang *et al.* 1982; Healey, 1984). Most of these include an age cut off, presence of bilateral shoulder girdle and hip girdle pain, morning stiffness and elevated markers of inflammation. Due to lack of any specific diagnostic tests for PMR, clinicians often use a prompt response to GCs as a confirmation of

the diagnosis. However, PMR can be mimicked by many other conditions, many of which also respond initially to glucocorticoids. Additionally, only 55-60% of patients with PMR respond completely to low dose GCs even after 3–4 weeks of therapy. Therefore GC responsiveness is no longer regarded as a cardinal feature of PMR [Hutchings *et al.* 2007; Dasgupta *et al.* 2012a, 2012b].

Given the diagnostic difficulty recent Classification criteria have been proposed by the European League against Rheumatism and the American College of Rheumatology (EULAR/ACR) as a research tool to identify patients with PMR [Dasgupta B *et al* 2012].

Consensus derived candidate criteria were evaluated in a 6-month prospective inception cohort study using the single eligibility criterion of new onset bilateral shoulder pain. The study recruited 125 patients with new-onset PMR and 169 non-PMR comparison subjects with conditions mimicking PMR. Potential criteria were assessed for their ability to discriminate PMR from other conditions and a scoring algorithm was developed. New-onset bilateral shoulder pain in subjects aged 50 years or older and elevation of CRP and/or ESR are regarded as essential items for classification as PMR. (Dasgupta B *et al* 2012).

The EULAR/ACR criteria include three required and four additional criteria. A scoring algorithm was developed with four additional criteria items (see table 1).

A score of 4 or greater had 68% sensitivity and 78% specificity for discriminating all comparison subjects from PMR. The specificity was higher (88%) for discriminating shoulder conditions from PMR and lower (65%) for discriminating RA from PMR. The positive predictive value was 69% and the negative predictive value was 77%

Table 1. The EULAR/ACR criteria

Required Criteria = 3	Additional criteria
age ≥50 years	morning stiffness ≥45 minutes = 2 points
bilateral shoulder aching	Pain or limited range of motion at the hip= 1 point
abnormal CRP or ESR	Absence of RF or anti-CCP = 2 points
	Absence of peripheral joint pain = 1 point

One study compared the performance of the EULAR/ACR criteria with other previously published classification criteria in 136 patients with PMR and 149 controls with rheumatoid arthritis and other inflammatory arthritides [Macchioni P 2014].

The EULAR/ACR criteria were the most sensitive (93 percent), although they were not the most specific (82 percent). In addition to clinical features the inclusion of shoulder and hip ultrasound in the EULAR/ACR criteria increased specificity to 91 percent, see Table 2.

Table 2: 2012 EULAR ACR Classification criteria

Polymyalgia rheumatica classification criteria: scoring algorithm. Required criteria: age \geq 50 years, bilateral shoulder aching, and abnormal CRP and/or ESR^a

	Points without US 0–6	Points with US ^b 0–8
Morning stiffness >45 minutes	2	2
Hip pain or limited range of motion	1	1
Normal RF or ACPA	2	2
Absence of other joint involvement	1	1
At least 1 shoulder with sub deltoid bursitis and/or biceps tenosynovitis and/or glenohumeral synovitis (either posterior or axillary) AND at least 1 hip with synovitis and/or trochanteric bursitis	Not applicable	1
Both shoulders with sub deltoid bursitis, biceps tenosynovitis or glenohumeral synovitis	Not applicable	1

^a A score of 4 or more is categorized as PMR in the algorithm without US and a score of 5 or more is categorized as PMR in the algorithm with US.

^b Optional ultrasound criteria.

Ultrasound was performed in 120 PMR subjects, 154 comparison subjects (46 with RA and 47 with shoulder conditions), and 21 additional controls who did not have shoulder conditions. Patients with PMR were more likely to have abnormal ultrasound findings in the shoulder (particularly sub deltoid bursitis and biceps tenosynovitis), and somewhat more likely to have abnormal findings in the hips than comparison subjects as a group. PMR could not be distinguished from RA based on ultrasound, but could be distinguished from non-RA shoulder conditions and subjects without shoulder conditions. Adding ultrasound criteria of either both shoulders and/or a shoulder and hip showing typical abnormalities, an algorithm score of 5 or more has 66% sensitivity and 81% specificity for discriminating all comparison subjects from PMR. Ultrasound abnormalities at presentation were also predictive of a good steroid response.

In the absence of alternative diagnoses, a score of 4 or greater (without ultrasound), or 5 or greater (with ultrasound) is indicative of PMR. Patients with a score of less than 4 (based on clinical plus laboratory criteria) cannot be considered to have PMR and need further diagnostic workup. Ultrasound improves the specificity of PMR diagnosis, and shows particularly good performance in differentiating PMR from non-inflammatory conditions and thus is a recommended investigation for PMR.

2 Classification criteria for GCA

Criteria for the classification of GCA were developed by the ACR in 1990, Table 3 (Hunder et al, 1990). They were designed to differentiate GCA from other vasculitides and are thus not useful for diagnosing GCA in individual cases in which GCA must also be differentiated from non-vasculitic diseases. The recent use of imaging has increased our understanding that GCA is a spectrum of overlapping phenotypes and it encompasses classical cranial arteritis and extra – cranial GCA, also referred to as large vessel GCA (GCA- LVV). Temporal artery biopsy (TAB) remains the ‘gold standard’ for the diagnosis of GCA, although about 10–20% of TABs in patients with GCA are negative. Imaging methods are increasingly used for the diagnosis of GCA (Dejaco C 2011). When possible, a TAB or ultrasound scan should be performed before starting treatment. However, TAB specimens may show arteritis after more than 2 weeks of glucocorticoid therapy.

Table 3: American College of Rheumatology classification criteria for giant cell arteritis

Original Criteria	Additional Suggested criteria
Age at disease onset ≥50 years: New headache: new onset or new type of localised pain in the head	Visual symptoms, sight loss, PMR, Constitutional symptoms, Jaw and or claudication
Temporal artery abnormality (temporal artery tenderness to palpation or decreased pulsation, unrelated to arteriosclerosis)	And or extra cranial arteries, decreased pulsation, bruits of extra – cranial arteries unrelated to arteriosclerosis
ESR ≥50 mm/hour	CRP > 10 mg/L
Abnormal artery biopsy: biopsy specimen with artery showing vasculitis characterised by a predominance of mononuclear cell infiltration or granulomatous inflammation, usually with multinucleated giant cells	And or abnormal imaging (US, MRI and or FDG PET)
<i>GCA is diagnosed if at least three of these five criteria are present.</i>	

3 Epidemiology

GCA is the most common type of vasculitis in Europe and North America, especially in people aged >70 years (Salvarani et al, 1995a; Salvarani et al, 1995b; Gonzalez-Gay et al, 2009b*; Gonzalez-Gay et al, 2010a). It mainly affects white people and almost exclusively occurs in subjects aged >50 years. Incidence increases with age and peaks in the 70–79-year-old age group. Women are affected two to three times more commonly than are men. However, a lower ratio of women to men was seen in Israel and Southern Europe (Gonzalez-Gay et al, 2009a*). It is likely that the occurrence of GCA will increase due to an aging population. The projected world-wide disease burden of GCA by 2050 is more than 3 million, and about 500,000 people will become visually impaired if the treatment is not adapted (De Smit E 2015).

The incidence of GCA increases with latitude in the Northern hemisphere (Baldursson et al, 1994). The highest incidence rates are reported in Scandinavian countries and in North American populations of Scandinavian descent (Franzen et al, 1992; Gran et al, 1997; Haugeberg et al, 2000). In these regions, the annual incidence is generally $>17/100\ 000$ population aged ≥ 50 years. However, the incidence of GCA is $<12/100\ 000$ population aged ≥ 50 years in Southern European and Mediterranean countries (Bas-Lando et al, 2007). A lower incidence of GCA was reported in Afro-American individuals from Tennessee (Smith et al, 1983). A very low annual incidence of GCA was reported in Turkey ($1.13/100\ 000$ people aged ≥ 50 years) (Pamuk et al, 2009). GCA was also found to be very uncommon in an Asian population: a nationwide survey in 1997 showed an extremely low prevalence of GCA in Japan of $1.47/100\ 000$ population aged ≥ 50 years (Kobayashi et al, 2003). A very low incidence of biopsy-proven GCA among Alaska natives ($\sim 1/100\ 000$ in those aged ≥ 50 years) was described (Mader et al, 2009).

It is possible that higher physician awareness may account for the progressive increase in GCA reported in different parts of the world (Nesher et al, 1996). In this regard, a reappraisal of the incidence of biopsy-proven GCA in the Lugo region of north-western Spain over the period 1981–2005 showed a progressive increase in the incidence of GCA (Gonzalez-Gay et al, 2007b).

As reported for GCA, the incidence of PMR has been found to be higher in subjects of Scandinavian background. Thus, the annual incidence of PMR in Ribe County, Denmark, over the period 1982–1985 was $68.3/100\ 000$ population aged ≥ 50 years (Boesen and Sorensen, 1987). Similarly, the annual incidence of PMR in Göteborg, Sweden, between 1985 and 1987 was $50/100\ 000$ population aged ≥ 50 years. Also, in Olmsted County, Minnesota (USA), where the population has a strong Scandinavian background, the annual incidence of PMR between 1970 and 1991 was $52.5/100\ 000$ population aged ≥ 50 years (Machado et al, 1988; Salvarani et al, 2004). However, as described for GCA, the annual incidence of PMR is lower in Southern European countries. The annual incidence of PMR in Reggio Emilia, Italy, over the period 1980–1988 was $12.7/100\ 000$ population aged ≥ 50 years (Salvarani et al, 1991). Likewise, the annual incidence in Lugo, Spain, for those aged ≥ 50 years during the period 1987–1996 was $18.7/100\ 000$ for overall PMR (associated or not with GCA) and $13.5/100\ 000$ for subjects with isolated ‘pure’ PMR (Gonzalez-Gay et al, 1999c).

4 Aetiology and pathogenesis

The aetiology of GCA and PMR is unknown. However, evidence suggests that both genetic susceptibility and environmental risks factors may play a role in the development of the disease.

4.1 Influence of environmental factors and infectious agents

A possible influence of environmental factors and infectious agents in the pathogenesis of GCA and PMR has been proposed. Simultaneous fluctuations in the incidence of GCA and PMR in different regions of Denmark

support an association with *Mycoplasma pneumoniae*, parvovirus B19 and *Chlamydia pneumoniae* epidemics (Elling et al, 1996). Other environmental agents that have been reported bacterial strains such as *Chlamydia* and *Burkholderia* or viruses such as parvovirus B19 and varicella-zoster virus. Regular cyclical and seasonal variations of GCA have been reported from several studies worldwide (Bird HA 1979, Mowat AG 1984, Cimmino MA 1990)

4.2 Role of genetic factors

A genetic component has been reported, particularly in patients with biopsy-proven GCA. Several genes within the major histocompatibility complex may have independent effects on susceptibility to GCA and PMR (Salvarani et al, 1991; Salvarani et al, 2000; Gonzalez-Gay et al, 2001a; Gonzalez-Gay et al, 2003; Gonzalez-Gay et al, 2004a; Gonzalez-Gay et al, 2007c). Thus, association with HLA-DRB1*04, TNF microsatellite polymorphisms MICA and HLA-B genes with genetic susceptibility to GCA have been suggested. Other studies have also reported that different genetic variants influence the key components of immune and inflammatory pathways in GCA and PMR susceptibility (Dababneh et al, 1998). In addition, a functional variant of the vascular endothelial growth factor gene has been associated with severe ischaemic complications in patients with GCA. On the other hand, a polymorphism of the intercellular adhesion molecule-1 has been associated with PMR and GCA susceptibility and conferred an increased risk of relapse in Italian patients with PMR (Amoli et al, 2002). The presence of both HLA-DRB1*0401 and some gene polymorphisms in the intercellular adhesion molecule-1 codon was also associated with an increased risk of relapses in patients with isolated PMR from north-western Spain. The first large-scale GCA genetic study, using the ImmunoChip platform, was published in 2013, and confirmed HLA-DRB1*04, followed by PTPN22 rs2476601, as the strongest genetic risk factors for GCA (Carmona FD 2015). The study also identified other putative risk loci for GCA involved in Th1, Th17, and Treg cell function. Collaborative efforts for larger, genome-wide association studies, involving international consortia from Europe, North America, and Australasia, are currently underway. New risk alleles such as plasminogen and P4H42 in GCA are also identified (Carmona FD 2017)

4.3 Influence of traditional cardiovascular risk factors

Some studies suggested an association between smoking and GCA. The presence of traditional risk factors for atherosclerosis before the diagnosis of the vasculitis—in particular, a history of hypertension, has also been found to increase the risk of developing severe ischaemic complications in GCA (Machado et al, 1989; Duhaut et al, 1998; Gonzalez-Gay et al, 2004f).

4.4 Pathogenesis

GCA is an antigen-driven disease with local T cell and macrophage activation in the vessel wall and proinflammatory cytokines playing an important role. Inflammation of the arterial wall and vessel occlusion

through rapid and concentric intimal hyperplasia (figure 1) lead to the severe ischaemic complications that may occur in patients with GCA. Dendritic cells localised at the adventitia–media border of normal large and medium arteries play a pivotal role in the initiation of the vasculitis process (Wagner et al, 2003; Weyand et al, 2005). These cells produce chemokines that recruit and locally activate T cells. Dendritic cells express a singular surface receptor profile, including a series of toll-like receptors (TLRs) (Ma-Krupa et al, 2005; Pryshchep et al, 2008). Ligands of TLR-4 promote activation and differentiation of adventitial dendritic cells into chemokine-producing effector cells with a high level of expression of both CD83 and CD86 and mediate T cell recruitment through release of pro-inflammatory cytokines. Activated T cells undergo clonal expansion and are stimulated to produce interferon gamma (IFN γ). This leads to the differentiation and migration of macrophages and the formation of giant cells. In the adventitia, macrophages produce proinflammatory cytokines such as IL-1 and IL-6, whereas in the media and intima they contribute to arterial injury by producing metalloproteinases and nitric oxide. This destructive mechanism of the arterial wall is associated with a repair mechanism that includes the secretion of growth and angiogenic factors (platelet-derived growth factor and vascular endothelial growth factor) through the infiltration of mononuclear cells and multinucleated giant cells (Rueda et al, 2005). These changes ultimately lead to the degradation of the internal elastic lamina and to occlusive luminal hyperplasia.

Figure 1 Normal temporal artery (left) and a temporal artery positive for giant cell arteritis (GCA) (right). Note the inflammatory infiltrate in the artery wall with intimal hyperplasia and luminal occlusion.

Although proinflammatory cytokines such as IL-1 and IL-6 are implicated in the pathogenesis of GCA and PMR, IFN γ specifically seems to play a key role in the pathogenesis of GCA and in the development of the severe ischaemic manifestations of this condition (Weyand et al, 1994; Weyand et al, 1997; Weyand and Goronzy, 1999; Weyand et al, 2004). High transcription of IFN γ mRNA was associated with the formation of giant cells and with evidence of cranial ischaemic symptoms in patients with GCA. Key cytokines involved in the pathogenesis of chronic inflammation, intimal hyperplasia and proliferation of vascular smooth muscle cells include interleukin-17 as well as PDGFA and B, VEGF, neurotrophins and endothelins which can increase sensitivity to vaso constriction.

In PMR, pathological findings are much less prominent than in GCA. The current concept is that GCA and PMR are the opposite ends of the same spectrum with the absence of vascular involvement in pure PMR. Bursitis, mainly involving the shoulders, is typical of PMR (Salvarani et al, 2002a; Salvarani et al, 2008a). Synovitis, bursitis, and tenosynovitis around the joints are all seen in PMR. Inflammation is initiated inside the tissue (synovium or bursa) with recognition of putative antigen by dendritic cells (DCs) or macrophages (Figure 1). Activated DCs or macrophages secrete inflammatory mediators, including IL-1, IL-6, and tumour necrosis factor alpha (TNF α), which are responsible for the systemic features of the disease. These cells migrate to central lymphoid organs where they present antigen to T cells, which then migrate to the synovium, enhance the adaptive immune response, and secrete further cytokines promoting local inflammation. Two different T-cell subsets, Th17 (steroid-sensitive acute lesions) and Th1 (steroid-insensitive chronic lesions) may relate to the persistence of disease in GCA and a similar mechanism for disease persistence may be relevant to PMR. Two different T-cell subsets, Th17 (steroid-sensitive acute lesions) and Th1 (steroid-insensitive chronic lesions) may relate to the persistence of disease in GCA (Deng J 2010). A similar mechanism for disease persistence may be relevant to PMR.

5 Clinical manifestations

5.1 Clinical manifestations of PMR

The hallmark features of PMR are proximal bilateral pain and stiffness in the shoulder and pelvic girdle in patients over the age of 50. The onset is usually abrupt. Typically, early morning stiffness lasts 30 min or longer. The patients usually also describe stiffness after periods of rest. Shoulder pain is reported by 75–99% of patients, whereas the hip girdle and neck are less often involved (50–90% of cases). Pain usually radiates distally towards the elbows and knees. It can be initially unilateral, but soon becomes bilateral. It is inflammatory and hence particularly associated with early morning disability and patients have problems getting out of bed and dressing, hygiene, reaching or rising from a chair. On examination, painful restriction of active and often passive movements of the shoulders and hips is present with or without detectable joint swelling. There can also be muscle tenderness. Constitutional manifestations such as low-grade fever, sweats, fatigue, and anorexia and weight loss occur in up to 40% of patients. However, high spiking fever is uncommon.

in PMR in the absence of GCA. Muscle weakness is not a feature of the disease, although it can be difficult to assess in the presence of muscle pain.

Some reports have emphasised the presence of distal musculoskeletal manifestations in patients with PMR. In a series of 177 patients with PMR, carpal tunnel syndrome was diagnosed in 14% of patients and distal tenosynovitis in 3%, while peripheral arthritis predominantly involving the knees and wrists with an asymmetrical pattern was seen in 25% of patients (Salvarani et al, 1998). However, it is uncommon for feet and ankles to be affected. Moreover, PMR-associated arthritis is non-erosive and usually remits after glucocorticoid therapy or after increasing glucocorticoid dosage.

There may also be an overlap with inflammatory arthritis. Peripheral arthritis in patients can be associated with RS3PE (remitting seronegative symmetrical synovitis with pitting oedema), a condition mainly characterised by joint synovitis and flexor tendon synovitis of the hands and feet. Symptoms promptly respond to small doses of glucocorticoids.

Musculoskeletal ache and pain mimicking PMR may occur in some malignancies—in particular, in multiple myeloma and solid malignancies such as renal adenocarcinoma. However, musculoskeletal manifestations associated with neoplasm differ from those of PMR, with more diffuse pain, absent or minimal morning stiffness, little if any proximal joint restriction, no shoulder bursitis on ultrasonography (US) and a poor response to glucocorticoid treatment. There is no association between typical PMR and malignancies.

PMR should be diagnosed by a step-wise approach using core inclusion criterion of proximal pain and stiffness, thereafter excluding infection, cancer, GCA and other rheumatological conditions with clinical evaluation and pertinent blood tests. Low dose steroids should be used only after receiving results of preliminary blood tests. Meticulous follow up is necessary to exclude late emergence of an alternative condition.

5.2 Clinical manifestations of GCA

GCA is now recognized as a clinically heterogeneous disease with a wide spectrum of features. Clinical features of GCA are mainly due to involvement of the cranial arteries (Gonzalez-Gay et al, 1992; Gonzalez-Gay et al, 2005c). Headache is the most frequent expression of this vasculitic process. New onset of headache, or changes in the pattern of a pre-existing headache, is the most common symptom, occurring in over 60% of patients with GCA. The headache is characteristically of sudden onset, severe and predominantly temporal. However, it may affect any part of the head, such as occipital, frontal and parietal regions. Scalp tenderness occurs in around a third to a half of patients and is usually noticed while brushing or combing the hair. The new onset of headache in a patient aged ≥ 50 years should alert the clinician to the possibility of GCA. Physical examination in GCA may reveal tenderness, thickening, nodules and occasionally redness of the superficial

temporal arteries (figure 2). Temporal artery pulses may be decreased or absent; extra-cranial arterial pulses should be examined including a search for bruits, particularly in the supra-aortic branches.

Some 40–50% of patients report jaw claudication (pain on chewing that improves after stopping mastication) due to ischemia of the masseter muscles, and about 7% of patients describe trismus. Ischemic jaw and tongue pain claudication is highly specific for GCA. Occasionally, intermittent claudication can affect the tongue or the muscles involved in swallowing, leading to tongue necrosis or dysphagia, respectively. Unilateral scalp necrosis due to involvement of the branches of the scalp arteries is occasionally seen.

Constitutional symptoms, such as fever, day and night sweats, anorexia, weight loss and fatigue, are present and often quite prominent (Calamia and Hunder, 1981; Gonzalez-Gay et al, 2004b; Gonzalez-Gay et al, 2004c) in the sub group of cases we now call large vessel GCA. This group often presents with polymyalgia and persistent high inflammatory markers. In some cases, they may be the only clinical manifestations of GCA. Fever is usually low grade, but it may exceed 38°C in about 10% of patients. Large vessel GCA may present as fever of unknown origin (FUO), and may account for up to 16% of cases of FUO in the elderly (Knockaert DC 1993)

Figure 3 Patient with giant cell arteritis. On physical examination, a segment of the right temporal artery is thickened and nodular and the temporal artery is tender on palpation. Patient consent obtained.

GCA is a major cause of irreversible visual loss. The incidence of ocular complications ranges from 14% to 70% in different series. Hayreh et al (1998) reported ocular manifestations in 50% of 170 patients with GCA. A lower incidence of ocular manifestations of 20–30%, often at disease onset, is reported in patients with GCA initially seen by a rheumatologist. In unselected patients with biopsy-proven GCA from north-western Spain, visual complications were found in 25% of cases, and irreversible visual loss in 15% of patients (Gonzalez-Gay et al, 1998a; Gonzalez-Gay et al, 2000a). Partial or total visual loss was found in 19% of patients with GCA from Reggio Emilia (Italy) (Salvarani et al, 2005a). Permanent irreversible sight loss usually occurs in the very elderly and in patients with co-morbidities.

The most common ophthalmic manifestation of GCA is anterior ischaemic optic neuropathy (AION) and it occurs almost always prior to glucocorticoid therapy. This is caused by interruption of blood flow in the posterior ciliary arteries to the optic nerve head. Patients usually have preceding jaw and/or tongue pain, visual symptoms such as diplopia, blurred vision or amaurosis fugax. Visual loss may present as a mist in the entire field or part of the visual field and evolve within 24–48 h to total blindness. One eye is affected first, but involvement of the other eye in untreated patients may occur 1–10 days after the initial event. In the acute phase of AION, the optic disc is pale and swollen but the retina is almost normal. Afterward, atrophy of the optic nerve associated with optic disc cupping is seen. Fundoscopy and fluorescein angiography usually demonstrates extensive choroidal hypoperfusion. More rarely, visual loss is caused by central retinal artery occlusion, ischaemic retro bulbar neuropathy or occipital infarction in association with a stroke involving the vertebrobasilar territory. When the arteritic process involves the central retinal artery leading to retinal stroke, the retina is primarily damaged and appears greyish and swollen, while a contrasting red zone can be seen in the macula—the so-called ‘cherry red spot’. In the extremely rare cases of blindness in GCA due to cortical ischemia, the optic disc appears unaffected on fundoscopy. The extent of sight loss can be significantly reduced by fast track GCA pathways and immediate start of high dose glucocorticoids.

In assessing a series of 84 consecutive patients with GCA, visual loss was due to AION in 91% of cases: central retinal occlusion was found in 10.5%, cilio retinal artery occlusion in 10% and/or posterior ischaemic optic neuropathy in 4%, either alone or in different combinations (Hayreh et al, 1998). AION was reported by Salvarani et al to be the cause of partial or permanent visual loss in 24 of 26 patients who had this complication (Salvarani et al, 2005a).

Amaurosis fugax has been reported to occur in 2–30% of patients with GCA. It is generally unilateral and it often precedes the development of visual loss. Amaurosis fugax was reported to precede the development of permanent visual loss in 12 of 24 cases from north-western Spain. It is the best clinical predictor of permanent visual loss. Diplopia is another ocular manifestation due to ischemia of the oculomotor nerves or the extra ocular muscles. In a series by Hayreh et al (1998), diplopia was observed in 5.9% of cases and was transient in all of them. In north-western Spain, diplopia was reported in 5.6% of patients.

About a third of all patients with GCA have evidence of large vessel vasculitis, which can be complicated by vascular stenosis, aortitis dissections and aneurysms (Martínez-Valle et al, 2010; Bossert et al, 2011; Garcia-Martinez et al, 2013). In a retrospective study from Olmsted County, Minnesota (USA), thoracic aorta aneurysms, abdominal aorta aneurysms and large vessel stenoses (predominantly affecting the upper limbs) were found in 11%, 10% and 13% of unselected patients with GCA, respectively (Nuenninghoff et al, 2003). These complications occurred on average 5, 6.3 and 1.1 years, respectively, after the onset of GCA. The incidences of aneurysmal disease per 1000 person-years in populations followed up in Olmsted County and north-western Spain were remarkably similar (18.7 in Olmsted County and 18.9 in north-western Spain) (Gonzalez-Gay et al, 2004d). Thoracic aortic aneurysmal disease was slightly more common in north-western Spain. In contrast, abdominal aortic aneurysmal disease was more common in Olmsted County.

Data obtained from prospective studies designed specifically to detect vascular stenoses and aneurysms in patients with GCA, show an even higher incidence of these complications. However, although stenoses and aneurysms occur relatively late in the course of GCA, large vessel inflammation has been demonstrated early on using sensitive imaging techniques. In a study of 35 newly diagnosed, untreated patients with GCA, 18F-fluorodeoxyglucose positron emission tomography (FDG/PET) showed large vessel vasculitis in 83% of cases (Blockmans et al, 2006). Another prospective study showed large artery disease in 29-83% with newly diagnosed GCA. (Muratore F 2015). In a recent prospective study of 54 GCA patients who underwent CT scan and ultrasound aortic structural damage affects up to 33.3% with maximal incidence within the first 5 years (Garcia – Martinez A 2014)

Several studies showed differences in clinical aspects when GCA patients with large vessel disease are compared with cranial involvement. They are likely to be younger, less likely to present with headaches and positive TAB. They have more constitutional symptoms, polymyalgia, persistent raised inflammatory markers and they generally require higher dose of GCs and frequently relapse (Muratore F 2015).

Other investigations such as colour Doppler ultrasonography (CDUS), CT and MRI can also record early large vessel vasculitis. Axillary artery intimal medial thickness on ultrasound is currently being investigated as a marker for large vessel involvement. Aortic murmurs and vascular bruits in the arms, as well as upper extremity claudication, are signs suspicious for large vessel involvement, while hypertension, hyperlipidaemia, PMR and coronary artery disease have been considered to be risk factors for the subsequent development of large vessel complications. Patients with active large vessel vasculitis should be treated with glucocorticoids, even in the absence of cranial vessel involvement, to prevent future complications.

Transient ischaemic attacks and strokes caused by severe obstruction or occlusion of the internal carotid artery or especially the vertebral arteries have been reported in around 3% of patients (Gonzalez-Gay et al,

2009b*). Inflammation of intracranial or intradural arteries is considered rare although recent studies with 3T and 7T MRI have shown involvement (Christina Goll 2016).

Visual manifestations, jaw claudication and cerebrovascular accident seem to be less common in patients with GCA with negative TAB than in patients with biopsy-proven GCA (Duhaut et al, 1999b).

Facial pain (González-Gay et al, 1998b) and swelling (Liozon et al, 2006) is another uncommon feature of GCA. Other facial manifestations include odontogenic pain, chin numbness, glossitis, submandibular swelling and necrosis of the scalp (Gonzalez-Gay et al, 2009a*; Gonzalez-Gay et al, 2009b*), tongue and lips. Some patients have carotidynia (pain felt over the carotid arteries) (Gonzalez-Gay et al, 1998c).

Finally, pericardial and pleural effusions (Valstar et al, 2003), myocardial infarction (Lie et al, 1986), female genital tract and breast involvement (Bajocchi et al, 2007), inappropriate antidiuretic secretion syndrome (Luzar et al, 1982) and dysarthria (Lee et al, 1999) have been occasionally reported as presenting features.

5.3 Association between PMR and GCA and LVV

Both PMR and GCA are characterised by onset at over 50 years of age, with progressively increasing incidence with older age, a higher prevalence in women, a systemic inflammatory response and generally good response to glucocorticoid therapy (Rodriguez-Valverde et al, 1997; González-Gay et al, 1998a; Gonzalez-Gay et al, 2004e). The incidence of both conditions peaks in patients above 70 years of age. Patients with GCA often present clinical manifestations of PMR. In biopsy-proven GCA, PMR manifestations are found in up to 50% of cases. PMR may be the presenting feature in patients who later develop the typical cranial manifestations of GCA (Narvaez et al, 2015). Also, PMR and GCA may appear simultaneously or PMR may develop after clinical manifestations of GCA are evident. Different population-based studies have shown the presence of biopsy-proven GCA in 16–21% of patients with PMR. In a part of Italy, during the period 1996–2000, 12/76 (16%) patients with PMR from Prato, had histological evidence of GCA. However, only one (1.3%) of these 76 patients with PMR had a positive TAB without any clinical feature of GCA. In the remaining 11 patients with PMR, cranial manifestations of GCA were present at the time of biopsy. In northwestern Spain, 9% of patients presenting with isolated ‘pure’ PMR had a positive TAB. A population-based study conducted to establish differences between isolated PMR and PMR in the setting of biopsy-proven GCA, disclosed that the patients in the former group were significantly younger than those with PMR associated with biopsy-proven GCA. Patients with isolated PMR had a lower frequency of asthenia, anorexia and weight loss, and seemed to have a milder inflammatory disease as shown by significantly less abnormality in the majority of laboratory findings (Gonzalez-Gay et al, 1998e). Clinically silent arteritis has been observed in patients initially diagnosed as having isolated PMR (Gonzalez-Gay et al, 2004c). Abnormal vascular uptake was observed using PET in 31% of patients with PMR without clinico-histological evidence of GCA, although the uptake seen in PMR was less intense than that seen in GCA (Blockmans et al, 2007).

LV-GCA occurs in up to 83% of patients with GCA and with unknown frequency in PMR. The possibility

Of coexistent GCA arises in PMR patients with incomplete GC response, constitutional symptoms and markedly elevated acute phase reactants (Blockmans D 2006, Prieto-Gonzalez S. *et al* 2012).

LV-GCA may be present at diagnosis, and may occur at any point during the disease course, and is detected with increasing frequency in GCA patients after 4 to 5 years of disease (Kermani T 2013). The definition of LV GCA is still imprecise, which hampers the performance of proper epidemiological studies. A biopsy of larger Arteries is not feasible in routine practice, and LV-GCA diagnosis is thus based on imaging methods such as axillary ultrasound, ¹⁸F-fluorodeoxy-glucose positron emission tomography (¹⁸F-FDG–PET), computed tomography angiography (CTA) or magnetic resonance imaging (MRI) to assess mural inflammation and changes in the lumen.

The new understanding of GCA as a disease complex that is not limited to cranial arteries, along with advanced imaging techniques and international efforts to better define the disease will facilitate future studies on the epidemiology of GCA, permitting better understanding of its incidence, prevalence and disease course.

Table 4: Clinical spectrum of GCA /PMR and Large Vessels Vasculitis (LVV)

Clinical features	Cranial GCA	LV-GCA	PMR
Headache	Present	Absent	Absent
Scalp tenderness, artery thickening	Present	Present	Absent
Jaw claudication	Present	Absent	Absent
Visual symptoms	Present	Absent	Absent
Constitutional symptoms	mild	Mod - severe	Mod-severe
Arm claudication	Present	Prominent feature	Not a feature
polymyalgic	mild	Mod- severe	severe
Acute phase reactants	Present	Present	Present
Peripheral arthritis/RS3PE	May occur	May occur	Mostly associated

Some studies showed that patients with coexisting GCA and PMR may need longer glucocorticoid treatment than those with GCA or PMR alone.

6 Laboratory investigations

For years, a high erythrocyte sedimentation rate (ESR) has been considered a hallmark for the diagnosis of GCA or PMR. Raised inflammatory indices such as ESR and C-reactive protein (CRP) support the diagnosis of PMR

and GCA and can also be used to monitor disease activity over time (Andersson et al, 1986; Kyle et al, 1993; Cantini et al, 2000; Gonzalez-Gay et al, 2005a). CRP may be a more sensitive indicator of disease activity than ESR in PMR and GCA. However, it is not clear whether CRP or ESR is better in clinical practice for the diagnosis of PMR and GCA. An ESR <40 mm/1st h is very uncommon in PMR and in GCA. In a population-based study of a series of patients with biopsy-proven GCA, only one of the 240 patients had an ESR <40 mm/1st h and the median ESR value were 93 mm/1st h (Salvarani and Hunder, 2001). In this same series, 97% of patients had a CRP >5 mg/L at the time of diagnosis and the median CRP was 83 mg/L. Therefore, normal ESR and CRP values make a diagnosis of GCA very unlikely. In a population-based study of 273 patients with biopsy-proven GCA, only 10 (3.6%) had an ESR <50 mm/1st h. But a normal ESR and a normal CRP does not rule out GCA. A biopsy-proven ocular complicated case of GCA with a normal ESR and CRP has recently been reported (McAlinden et al, 2014*). Patients with isolated PMR and low ESR have also been described (Gonzalez-Gay et al, 1997b).

Significant differences in the frequency of visual ischaemic complications were observed according to different ESR levels (Cid et al, 1998; Hernández-Rodríguez et al, 2002). In one study (Lopez-Diaz et al, 2008b); there was an increased frequency of visual ischaemic events in the subgroup of patients with biopsy-proven GCA with an ESR between 70 and 100/1st h at the time of diagnosis. Twenty-five (21%) of 120 subjects with ESR values between 70 and 100 mm/h experienced permanent visual loss compared with only 10 (7%) of the remaining 153 patients (10 with an initial ESR <50 mm/1st h, 28 with an ESR between 50 and 69 mm/1st h, 115 with an ESR >100 mm/1st h). In this study an ESR between 70 and 100 mm/1st h was the best predictor of visual ischaemic complications and irreversible visual loss. But in another population-based study of 180 patients with biopsy-proven GCA, ESR and CRP values at diagnosis were significantly lower in patients with cranial ischaemic events, including permanent visual loss. Other studies have emphasised the protective role of a strong inflammatory response (constitutional symptoms, fever and very high inflammatory markers) against the development of ischaemic complications, including loss of vision in GCA. Cid et al (1998) also found that the mean ESR was significantly reduced in patients with irreversible cranial ischaemic complications compared with the other patients with biopsy-proven GCA.

Normochromic-normocytic inflammatory anaemia is common and may be the presenting manifestation of GCA. Haemoglobin values <12 g/dL may be found in about 50% of patients at the time of diagnosis. High platelet counts have also been widely described in patients with GCA, but their frequency varies from one series to another. In north-western Spain, thrombocytosis (>400 000 platelets/mm³) was seen in 117 (48.8%) of 240 patients with biopsy-proven GCA. Leucocytosis, generally not severe, has also been described in almost one-third of patients with GCA.

Abnormal liver function tests—in particular, raised alkaline phosphatase, have also been described in these patients. Approximately one-quarter of patients with active GCA have a raised alkaline phosphatase, which normalises with glucocorticoid therapy.

Patients with GCA have positive tests for anticardiolipin antibodies more often than age- and gender-matched controls, but without an increased risk of thrombosis. Such anticardiolipin antibodies correlate, at least to some extent, with GCA activity and disappear after treatment onset (Manna et al, 1998; Liozon et al, 2000). A contribution of antiferritin antibodies to the diagnosis of GCA has been recently described but has not been widely confirmed and deserves further study (Baerlecken et al, 2012; Regent et al, 2013). IL-6 and BAFF cytokines have also been found to correlate with GCA disease activity (Van der Geest KS- 2015).⁷ Diagnosis of GCA and PMR.

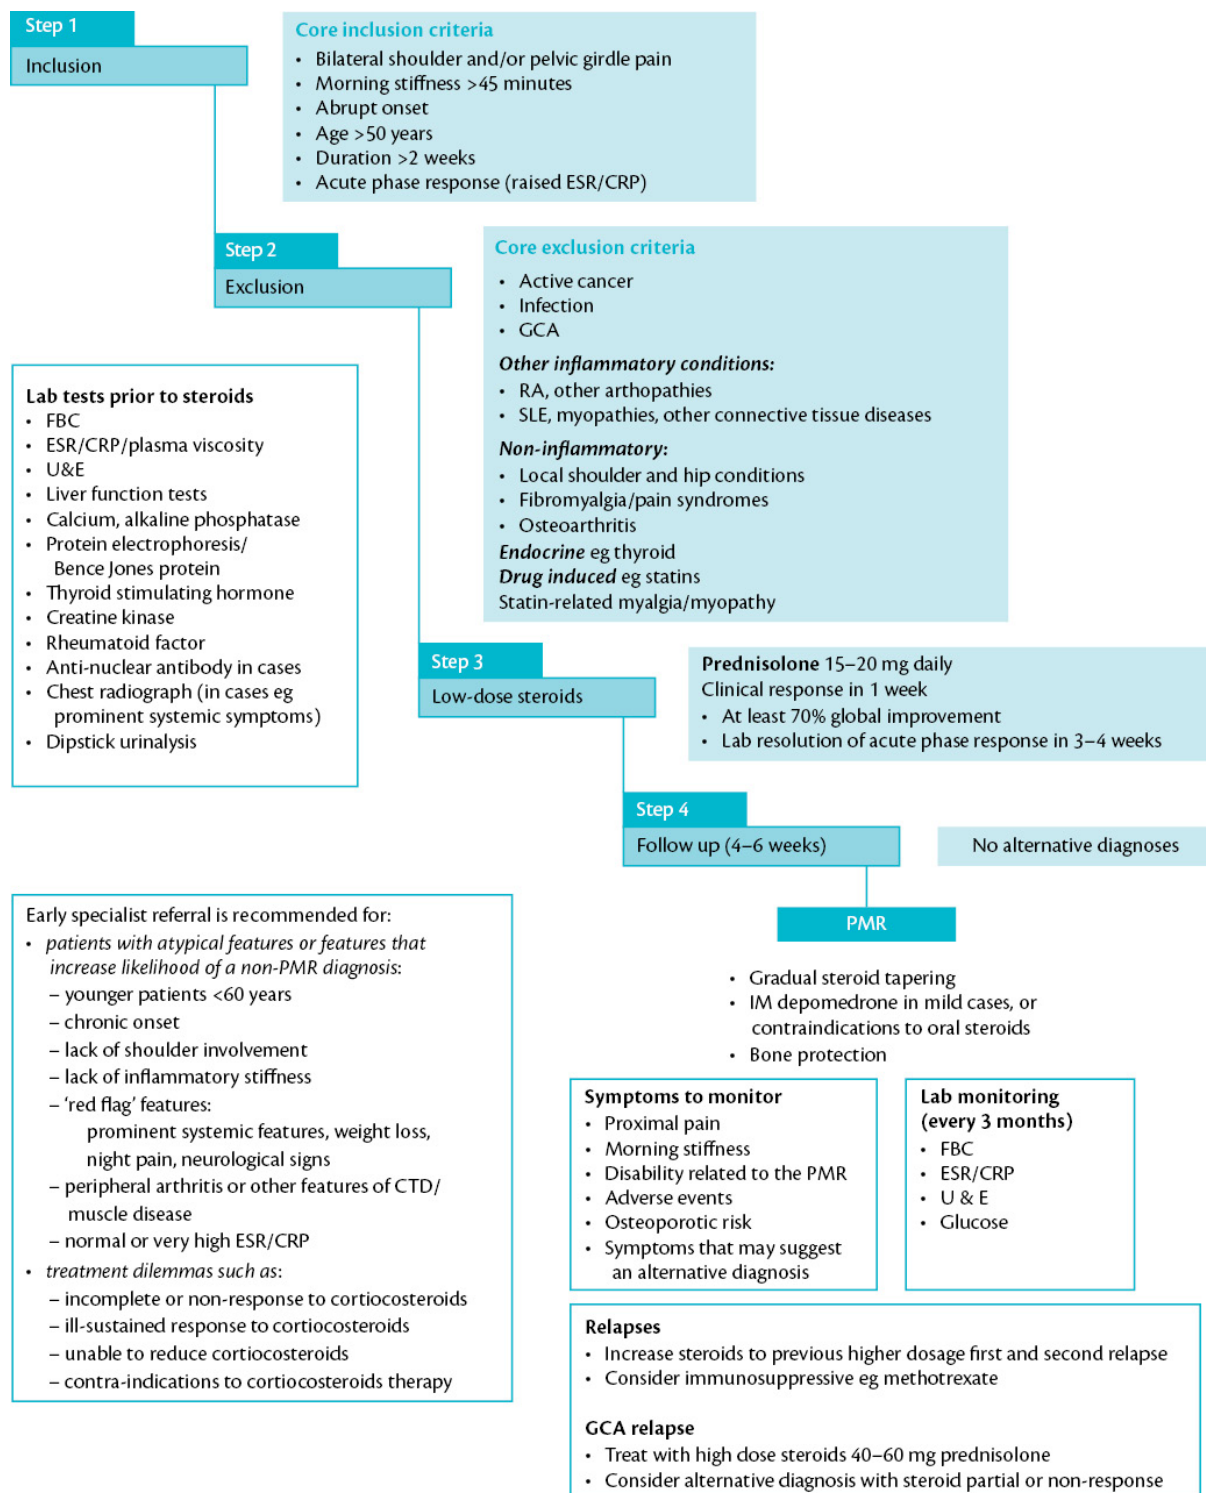

There are no definite diagnostic tests for PMR and even for GCA. The diagnosis is based on clinical presentation, exclusion of mimics, systemic inflammation and imaging. A stepwise approach for the diagnosis of PMR is recommended.

7.1 Temporal artery biopsy

TAB remains the ‘gold standard’ for diagnosis of GCA (Gonzalez-Gay et al, 2005b; Marí et al, 2009). A TAB is considered to be positive if there is interruption of the internal elastic laminae with infiltration of mononuclear cells into the arterial wall (figure 3). Intimal hyperplasia is a characteristic feature and its severity is associated with presence/absence of ischemic complications. Multinucleated giant cells are often seen (40–60% of cases), but their presence is not required for diagnosis. In some cases the inflammation is restricted to the vasa vasorum or to periadventitial small vessels, or both. The frequency of cranial ischaemic events of these groups of patients is similar to that of patients with classic GCA. Therefore, the clinician must also value this histological TAB pattern as proof of GCA and plan adequate treatment.

GCA affects vessels focally and segmentally, yielding areas of inflammatory vasculitic lesions juxtaposed with areas of normal artery. Because of skip inflammatory lesions, histological signs of inflammation may be missed in temporal artery biopsies performed in arteritis-free segments. As a consequence, in most series, 10–20% of temporal artery biopsies are reported to be negative in patients with GCA, although the rate may be as high as 40%. TAB findings have been reported as being negative in 42% of patients with large vessel involvement.

The best set of clinical features to predict a positive TAB in a community hospital is the association of headache, jaw claudication and abnormal temporal artery on palpation, with a significantly increased frequency of severe visual ischaemic complications (transient or permanent visual loss or diplopia) in patients with biopsy-proven GCA compared with patients with GCA with a negative TAB (Gonzalez-Gay et al, 2001b).

*Step approach flow chart is Reproduced with permission from clinical medicine, 2010; 10(3): 270-4. In the Lab investigations we now recommend adding ACPA. Drug induced PMR should include effects of immune checkpoints inhibitors.

Figure 4. (A) Disruption of the internal elastic lamina by inflammatory cells and (B) presence of multinucleated giant cells. GCA, giant cell arteritis.

A threshold length of 1.0 cm of post-formalin fixed arterial segment on biopsy was associated with increased diagnostic yield indicating GCA (Taylor-Gjevre et al, 2005). These authors recommended collecting a minimum TAB length of at least 1.5 cm to allow for an estimated 10% tissue shrinkage during fixation. A post-formalin fixed TAB length of at least 0.5 cm could be sufficient to make a histological diagnosis of GCA (Mahr et al, 2006). A review of 305 TAB reports for 173 patients showed that the TAB segments in the biopsy-positive patients were significantly longer than in biopsy-negative cases (Breuer et al, 2009b). These authors suggested that increasing post-fixation TAB length beyond 20 mm might further increase the rate of positive biopsies.

TAB should be performed on the most symptomatic site. Colour duplex sonography-guided TAB did not improve the sensitivity of TAB for diagnosing GCA (Germano et al, 2014*). A contralateral biopsy is not required unless the original biopsy was sub-optimal.

BSR and EULAR recommendations emphasise that a TAB should be performed soon after the onset of treatment whenever a diagnosis of GCA is suspected. However studies suggest that 2 – 4 weeks of prior glucocorticoid treatment does not affect the likelihood of a positive result (Narvaez J 2007)

7.2 Imaging studies in PMR

US, MRI and PET have been used in PMR to detect synovitis in proximal joints and periarticular structures and may help with diagnosis. Bilateral subacromial/sub deltoid bursitis and trochanteric bursitis are the most common lesions in most patients with PMR who have pain in the shoulder or pelvic girdle, respectively (Cantini et al, 2001b; Pipitone et al, 2008a; Pipitone et al, 2008b; Macchioni et al, 2009, Dasgupta et al 2012). See Figures 5, 6, 7, and 8. US and MRI are equally effective in confirming the presence of these lesions with a sensitivity and specificity of >90% (Cantini et al, 2004). US evidence of bilateral shoulder bursitis may support

the diagnosis of PMR in patients with normal or subnormal ESR. Shoulder US inflammatory findings are associated with better response to glucocorticoid therapy; milder US signs may persist even in those patients who achieve clinical response to treatment. Although shoulder bursitis is highly suggestive of PMR, it is not specific. In a study comparing patients with PMR with those with rheumatoid arthritis (RA) and psoriatic arthritis, bilateral subacromial/sub deltoid bursitis was found in all patients with PMR, but also in 20% of patients with RA, while glenohumeral synovitis was present in all patients. Bursitis has also been shown to be associated with neck or lumbar pain in PMR. In a study of 12 patients with new-onset, untreated PMR, interspinous cervical bursitis was found using MRI in all (Salvarani et al, 2008a). A subset of patients with rheumatologist-diagnosed PMR seem to have a characteristic, extra capsular pattern of MRI inflammation, especially around the hips, associated with elevated IL-6/CRP and with complete patient-reported glucocorticoid responsiveness (Mackie et al, 2016).

FDG/PET may be useful for detecting large vessel vasculitis in some patients presenting with PMR features (Blockmans et al, 2007): (a) patients with PMR for whom glucocorticoids do not produce an adequate response; (b) patients with PMR and persistently raised inflammatory markers and (c) patients with PMR and severe constitutional symptoms.

Plain X-ray examinations are not useful for diagnosing PMR, but the presence of erosions, chondrolysis or chondrocalcinosis in peripheral joints shifts the diagnosis away from PMR towards another diagnosis of arthritis.

7.3 Imaging studies in GCA

Imaging modalities such as CDUS, CT Angiography, MR Angiography and 18F FDG-PET are emerging as important diagnostic methods and are also useful for assessment of disease activity.

High-resolution CDUS has gained widespread acceptance as a diagnostic tool in GCA. Available CDUS transducers have a resolution of about 0.1 mm, which is 10-fold higher than that of MRI. CDUS can visualise both the vessel wall and the lumen, and may thus demonstrate early vessel wall alterations while the lumen is still unaffected. Other advantages of CDUS include its limited cost, non-invasive nature, the relatively short time required for the investigation and the absence of exposure to ionising radiation.

The use of CDUS in GCA was initiated by Schmidt et al, who showed that inflamed temporal arteries in GCA have a concentric hypoechogenic mural thickening, called a 'halo', which the authors interpreted as resulting from inflammatory vessel wall oedema (Schmidt et al, 1997). The authors reported that the halo sign had a specificity of 100% and a sensitivity of 73% for the diagnosis of GCA, whereas stenoses and occlusions, although common (80% of cases), were less sensitive and specific for GCA. Since then, CDUS has increasingly been used to screen patients with suspected GCA. A meta-analysis of studies published up to 2004 reported a sensitivity of 69% and a specificity of 82% for the halo sign in the temporal arteries for GCA with a positive TAB, and a sensitivity and a specificity of 55% and 94%, respectively, for GCA diagnosed according to the ACR criteria (Karassa et al, 2005). A meta-analysis of prospective studies published through 2009 that examined the CDUS findings of the temporal arteries of patients with suspected GCA using the ACR 1990 classification criteria for GCA as the reference standard, yielded similar results (Arida et al, 2010). More specifically, a positive unilateral halo sign had an overall sensitivity of 68% and a specificity of 91% for GCA, while bilateral halo signs had a sensitivity of 43% and a specificity of 100%. Therefore, while a positive halo sign suggests a diagnosis of GCA in the presence of compatible clinical manifestations, the absence of a halo does not rule it out. In addition, the presence of a bilateral halo sign appears to have a very high specificity for GCA. The Compression sign – a non-compressible halo with persistence of hypoechoic wall swelling despite compression of involved vessel – is now considered a pathognomonic sign of GCA.

Schmidt et al compared the results of temporal artery US examinations with the occurrence of visual ischaemic complications in patients with GCA: anterior ischaemic optic neuropathy, central retinal artery occlusion, branch retinal artery occlusion, diplopia or amaurosis fugax in 222 consecutive patients with newly diagnosed, active GCA (Schmidt et al, 2009). However, the findings of temporal artery US did not correlate with eye complications.

US may also be useful to detect stenosis and occlusion, particularly helpful in detecting axillary and subclavian arteries. Studies have shown abnormalities of axillary arteries in 53% in GCA patients. (Khan A 2015, Czihal M 2012). The sonographic finding is distinct from arteriosclerotic lesions which are irregularly delineated, non-

homogeneous and or calcified wall alterations where as in GCA the abnormalities are circumferential, homogeneous, hypoechogenic thickening of the vessel wall. TABUL study which was a multicentre prospective study of 381 patients, comparing TAB to ultrasound of temporal and axillary arteries for diagnosis of newly suspected GCA, reported that ultrasound had a higher sensitivity for the diagnosis of GCA (54% vs. 39%) than TAB, but a lower specificity (81% vs. 100%) (Luqmani R 2015).

Inflammation of the aorta and its branches may occur in a subset of patients with GCA, although symptoms of aortic involvement can appear years after the initial diagnosis. Therefore, a systematic evaluation of patients with imaging techniques such as MRI, angiography and PET may show that the clinical impact of extracranial involvement in GCA is more than previously thought.

MRI can aid in diagnosing early large vessel vasculitis in GCA. Typical changes in inflamed vessels include thickening and oedema of the vessel wall, which precede the development of angiographically detectable stenoses or aneurysms. Magnetic resonance angiography is used to show alterations in the vessel lumen, such as stenoses and aneurysms. The main limitations of MRI are misinterpretation of vascular branch-points as occlusions, and falsely accentuated stenoses. MRI and CT are particularly useful in evaluating deep, large vessels such as the thoracic and the abdominal aorta, which are frequently involved in GCA.

Some data suggest that high-field strength MRI (3 T or 7T) may also be both sensitive and specific in demonstrating temporal artery inflammation. In the presence of inflammation, the temporal arteries show increased mural thickness and contrast enhancement within and around the vessel wall. Enhanced 3 T MR T2-weighted inversion recovery fast spin echo images have been shown to reveal mural oedema of inflamed cranial arteries, although with a lower diagnostic sensitivity than with contrast-enhanced images. Validation of these findings in large prospective trials is required, especially due to the limited availability of 3T equipment.

Theoretically, MRI could be useful for the diagnosis and also the follow-up of patients with GCA (Bley et al, 2005a; Bley et al, 2005b). However, very few longitudinal studies on patients with GCA monitored with sequential MRI have been carried out. A marked improvement in MRI inflammatory changes has been seen 8 weeks after starting glucocorticoid therapy. However, MRI has no clear role in following up large vessel vasculitis since correlation between MRI findings and clinical and laboratory parameters is poor.

Bley et al compared the results of high-resolution MRI and CDUS in 59 patients with suspected GCA with the final clinical diagnosis based on the ACR classification criteria for GCA (Bley et al, 2008). Thirty-six of the 59 patients (61%) were diagnosed as having GCA. The sensitivity of high-resolution MRI and CDUS was 69% and 67%, respectively, while specificity was 91% in both. TAB findings were positive in 24 of the 41 biopsied patients (59%). The sensitivity of high-resolution MRI and CDUS compared with TAB was 83% and 79%, respectively, and specificity was 71% and 59%, respectively.

FDG/PET can be used to secure the diagnosis of large vessel GCA because of its ability to disclose inflammatory cell infiltration of the vessel wall, which is one of the earliest events characterising large vessel vasculitis (Meller et al, 2003; Moosig et al, 2004; Besson et al, 2011; Prieto-Gonzalez et al, 2014*). However, owing to the high background uptake of FDG in the brain, PET is not helpful for the evaluation of medium vessels (temporal arteries and cranial arteries), and does not provide information about wall structure or luminal flow. In a study of 35 patients with new-onset, untreated GCA, increased vascular FDG uptake was seen in 83% of patients, mainly in the subclavian arteries (74%), the aorta (>50%) and the femoral arteries (37%) (Blockmans et al, 2006). An advantage of PET compared with other imaging modalities is that it can show both the severity and the extent of inflammation. In addition, PET can also be used to assess disease activity over time, including response to treatment. In a study performed in five untreated patients with active large vessel vasculitis and after treatment-induced remission, PET was positive in all patients, but FDG uptake clearly decreased compared with baseline in all patients in remission. In another study of four patients with large vessel vasculitis, glucocorticoid therapy led to clinical and laboratory improvement and significantly reduced tracer uptake in all patients, while the mean number of involved segments decreased from 28 to 15. However, in spite of the decreased FDG uptake, it does not disappear in most cases after treatment and other studies have shown an inconsistent correlation between the PET findings and the clinical and laboratory data as well as the MRI images. Therefore, the role of PET in the follow-up of patients with GCA remains unclear. Nevertheless, PET may be more sensitive than MRI in detecting vessel inflammation in the early stage of large vessel vasculitis

Figure 10: Hypoechoic halos surrounding the vessel lumen

Figure 11: Longitudinal and transverse view – halo sign is visible, hypoechoic homogeneous circumferential.

Figure 12: Top left –Longitudinal view of the Axillary artery, increased Intima-medial thickness. Top right shows positive PET scan. Bottom Left and right shows Intima-medial thickness of the axillary artery.

Figure 13: 18 F-Fluorodeoxyglucose positron emission tomography showing the presence of aortitis in a patient with polymyalgia rheumatica with a poor response to low-dose prednisone

There are limited data on the ability of PET to predict the development of complications in vessel segments. However, a study suggested that patients with GCA with increased FDG uptake in the aorta may be more prone to develop thoracic aortic dilatation than patients with GCA without this sign of aortic involvement.

Vascular uptake on PET is not specific for large vessel vasculitis. In a retrospective analysis of 137 patients who underwent PET for various reasons, older patients were found to have increased vascular FDG uptake judged to be secondary to age-related vessel changes, including atherosclerosis. Some characteristics may help to discriminate between atherosclerotic and vasculitic lesions. The vasculitic lesions are usually smooth and linear with an intense FDG uptake, whereas atherosclerotic plaques have a more irregular appearance ('hot spots') with less intense FDG uptake. In addition, the involvement of vessels usually spared by atherosclerosis should raise the suspicion of vasculitis.

Limitations of PET include the lack of visualisation of the temporal and renal arteries, the high costs of the procedure and it's (at the present time) limited availability.

8 Differential diagnosis of PMR and GCA

8.1 Differential diagnoses of PMR

Although the symptoms are very characteristic, several autoimmune disorders, infections, endocrine and malignant disorders can present with similar symptoms and in people aged <60 years inflammatory rheumatic diseases that mimic PMR are more common than PMR itself (table 1) (Gonzalez-Gay et al, 1999a; Gonzalez-Gay et al, 2000b; Gonzalez-Gay et al, 2004c). In particular, PMR should be differentiated from rheumatoid arthritis (especially, elderly-onset rheumatoid arthritis (EORA), late-onset spondyloarthritis (SpA) (Olivieri et al, 2007), calcium pyrophosphate deposition disease (CPPD) (Pego-Reigosa et al, 2005), fibromyalgia, viral myalgia, infective endocarditis (Gonzalez-Juanatey et al, 2001), bilateral rotator cuff syndrome, bilateral adhesive capsulitis ('frozen shoulder'), osteoarthritis of the cervical spine and shoulders, polymyositis, neoplasms including multiple myeloma, hypothyroidism (Ozdogan et al, 2005), late-onset systemic lupus erythematosus (SLE) and Parkinson's disease.

The differential diagnosis between early PMR and EORA is challenging because of a significant overlap of clinical and laboratory findings (Cutolo et al, 2009). Some patients with PMR develop peripheral non-erosive arthritis or tenosynovitis with a carpal tunnel syndrome. Conversely, an initial clinical presentation resembling PMR with marked shoulder involvement is four times more common in EORA than in adult-onset RA. The demonstration of anticitrullinated protein antibodies (ACPA) in elderly patients with inflammatory joint pain also supports the diagnosis of EORA over that of PMR. In one study, 65% of patients with EORA were reported as having ACPA, compared with none of the patients with PMR (Lopez-Hoyos et al, 2004). Similarly, a positive rheumatoid factor, particularly at high titre, would indicate a diagnosis of RA, although the specificity of the rheumatoid factor for RA is lower than that of ACPA, particularly in the elderly. A rapid response to glucocorticoid therapy would also be in keeping with a diagnosis of PMR, although patients with EORA may also improve with glucocorticoids, albeit in a less dramatic fashion. In some cases, a correct diagnosis can only be established at follow-up. A longitudinal study has shown that 6–17% of patients initially labelled as having PMR develop RA over an average of 4 years. The development of joint erosions strongly supports a diagnosis of RA, since arthritis associated with PMR is benign and non-erosive. Similarly, extra-articular manifestations of RA, such as cutaneous nodules, can help to secure its diagnosis.

Table 5 Polymyalgia rheumatica: differential diagnosis and testing

Diagnosis	Clinical features
Inflammatory disorders	
Polymyalgia rheumatica	Age >50 years, predominantly proximal shoulder and hip girdle symptoms, symmetrical; non-erosive joint disease on radiography
Rheumatoid arthritis, especially EORA	Mainly distal joint symptoms; positive for rheumatoid factor and ACPA; erosive joint disease on radiography
Late-onset spondyloarthropathy, including ankylosing spondylitis, psoriatic arthritis	Predominantly low back stiffness and pain; may have large and distal joint symptoms; spinal ankylosis on radiography; psoriasis
Calcium pyrophosphate deposition disease	X-Rays chondrocalcinosis, synovioanalysis
RS3PE syndrome	Peripheral hand or foot pitting oedema
SLE, scleroderma, Sjögren's syndrome, vasculitis	Fatigue, stiffness, multisystem disease; presence of antinuclear antibodies, cytopenias (SLE) and antineutrophil cytoplasmic antibodies
Dermatomyositis, polymyositis	Proximal muscle weakness, rash; high creatine kinase
Other disorders	
Osteoarthritis, spinal spondylosis	Joint pain in shoulder, neck and hips; gelling; degenerative changes on radiography
Rotator cuff disease, adhesive capsulitis (frozen shoulder)	Periarticular pain, restricted range of motion; ultrasound and MRI may show characteristic bursal and synovial inflammation
Infections, including infective endocarditis. Viral syndromes. Tuberculosis	Fever, weight loss, heart murmur, microscopic haematuria, blood cultures. Adapted tests.
Myeloma, lymphoma, leukaemia, occult solid tumours, amyloidosis	Weight loss, fatigue; investigations according to symptoms, sex and age; diffuse aching symptoms not limited to shoulder and hip girdles
Parkinsonism	Stiffness, rigidity, shuffling gait, gradual onset
Fibromyalgia, depression	Fatigue, longstanding pain, tender points, sadness, loss of usual interests
Hypovitaminosis D, osteomalacia, hyperparathyroidism, hyperthyroidism or hypothyroidism	Bone pain, fatigue, blood tests: vitamin D concentrations, parathyroid hormone, calcium, phosphorus, thyroid-stimulating hormone

ACPA, anti-cyclic citrullinated peptide; EORA, elderly-onset rheumatoid arthritis; RS3PE, remitting seronegative symmetrical synovitis with pitting oedema; SLE, systemic lupus erythematosus.

In addition to EORA, late-onset SpA should also be carefully considered in elderly patients with PMR-like manifestations since in this age group SpA may present with typical signs but also with constitutional manifestations, shoulder involvement and, sometimes, distal pitting oedema. The presence of predominant hip pain, sacroiliitis, axial involvement (with or without imaging signs), dactylitis, enthesitis, uveitis and extra-articular manifestations consistent with late-onset SpA (if present) can assist in making a correct diagnosis.

RS3PE can occur in association with PMR, but also with vasculitis, SpA or neoplasms, or be idiopathic. It should be distinguished from lymphoedema, usually found in association with RA or less frequently with psoriatic arthritis. Compared with RS3PE, lymphoedema has a harder feeling on palpation and does not respond to glucocorticoid therapy.

CPPD may occasionally present with polymyalgia-like symptoms. The identification of calcium pyrophosphate dihydrate crystals in the synovial fluid, the demonstration of the typical radiographic findings seen in CPPD, or both, can secure the correct diagnosis.

Late-onset SLE presenting as PMR has been previously reported. The presence of positive antinuclear antibodies in elderly individuals by itself does not exclude PMR. In patients with PMR the presence of leukopenia with lymphopenia and, especially, unexplained high titres of antinuclear antibodies, should prompt a more complete analytical study including proteinuria, anti-native DNA, anti-extractable nuclear antigen (anti-ENA), C3 and C4 laboratory tests. In these cases a detailed clinical history may be of help in eliciting symptoms related to SLE if present. A physical examination may also disclose clinical features such as pleuritis or pericarditis that are common in late-onset SLE which, together with the presence of haematological abnormalities such as leukopenia or thrombocytopenia, should raise suspicion of this condition.

Polymyositis presents with muscle pain, but early morning stiffness is not a feature of this condition, and above all, muscle strength, which is normal in PMR, is typically impaired in polymyositis. Laboratory tests, particularly a raised creatine kinase, and other investigations for muscle disease (if clinical necessary) (electromyography and muscle biopsy) allow confident discrimination of polymyositis from PMR.

Infective endocarditis may mimic PMR. Although fever may be a symptom of PMR in up to 35% of patients, other conditions presenting with fever and polymyalgia symptoms should be considered when there are reasons to suspect an underlying disease, particularly when there is little response to glucocorticoids. In this case, the possibility of an underlying systemic infection, even when fever is low grade, should be ruled out. The presence of unexplained malaise and low grade fever along with musculoskeletal manifestations are good reasons to exclude bacterial endocarditis that may cause musculoskeletal manifestations in up to 30% of patients (blood cultures must be performed if this diagnosis is evoked).

Viral myalgia can occur in the presence of various viral infections, and may be associated with systemic manifestations and raised inflammatory markers. However, viral myalgia is usually diffuse and quickly or rather quickly remits spontaneously.

Osteoarthritis of the cervical spine and shoulders is a common condition in the elderly population. Osteoarthritis of the acromioclavicular joints is associated with the growth of osteophytes impinging ('impingement syndrome') on the underlying rotator cuff, leading to rotator cuff damage and pain. The

combination of neck and shoulder pain can suggest PMR, but the mechanical characteristics of the pain, the absence of prolonged early morning stiffness and the normal inflammatory data assist in ruling out PMR.

Rotator cuff tendinitis can cause shoulder pain radiating down to the elbows, sometimes with nocturnal pain when lying on the affected shoulder. However, in rotator cuff tendinitis the symptoms are often initially unilateral (although they may become bilateral over time), pain is mechanical (although it may become inflammatory later on) and inflammatory markers are not raised.

Adhesive capsulitis ('frozen shoulder') rarely can mimic PMR when it affects both shoulders at the same time, since in the early stages the inflammatory pain dominates the clinical picture of adhesive capsulitis, and the typical restriction of joint movements (especially external rotation) occurs only weeks to months after disease onset. The absence of raised inflammatory markers and of bursitis on US can aid in differentiating adhesive capsulitis from PMR.

Neoplasms, particularly multiple myeloma and renal adenocarcinoma, can very occasionally present with PMR-like clinical features. However, in these cases there is usually limited or absent early morning stiffness, little if any proximal joint restriction, no evidence of bursitis or glenohumeral synovitis in the shoulder on US and poor response to low-dose glucocorticoid treatment. Some patients with a cancer have a paraneoplastic polyarthritis, as may patients with a myelodysplasia.

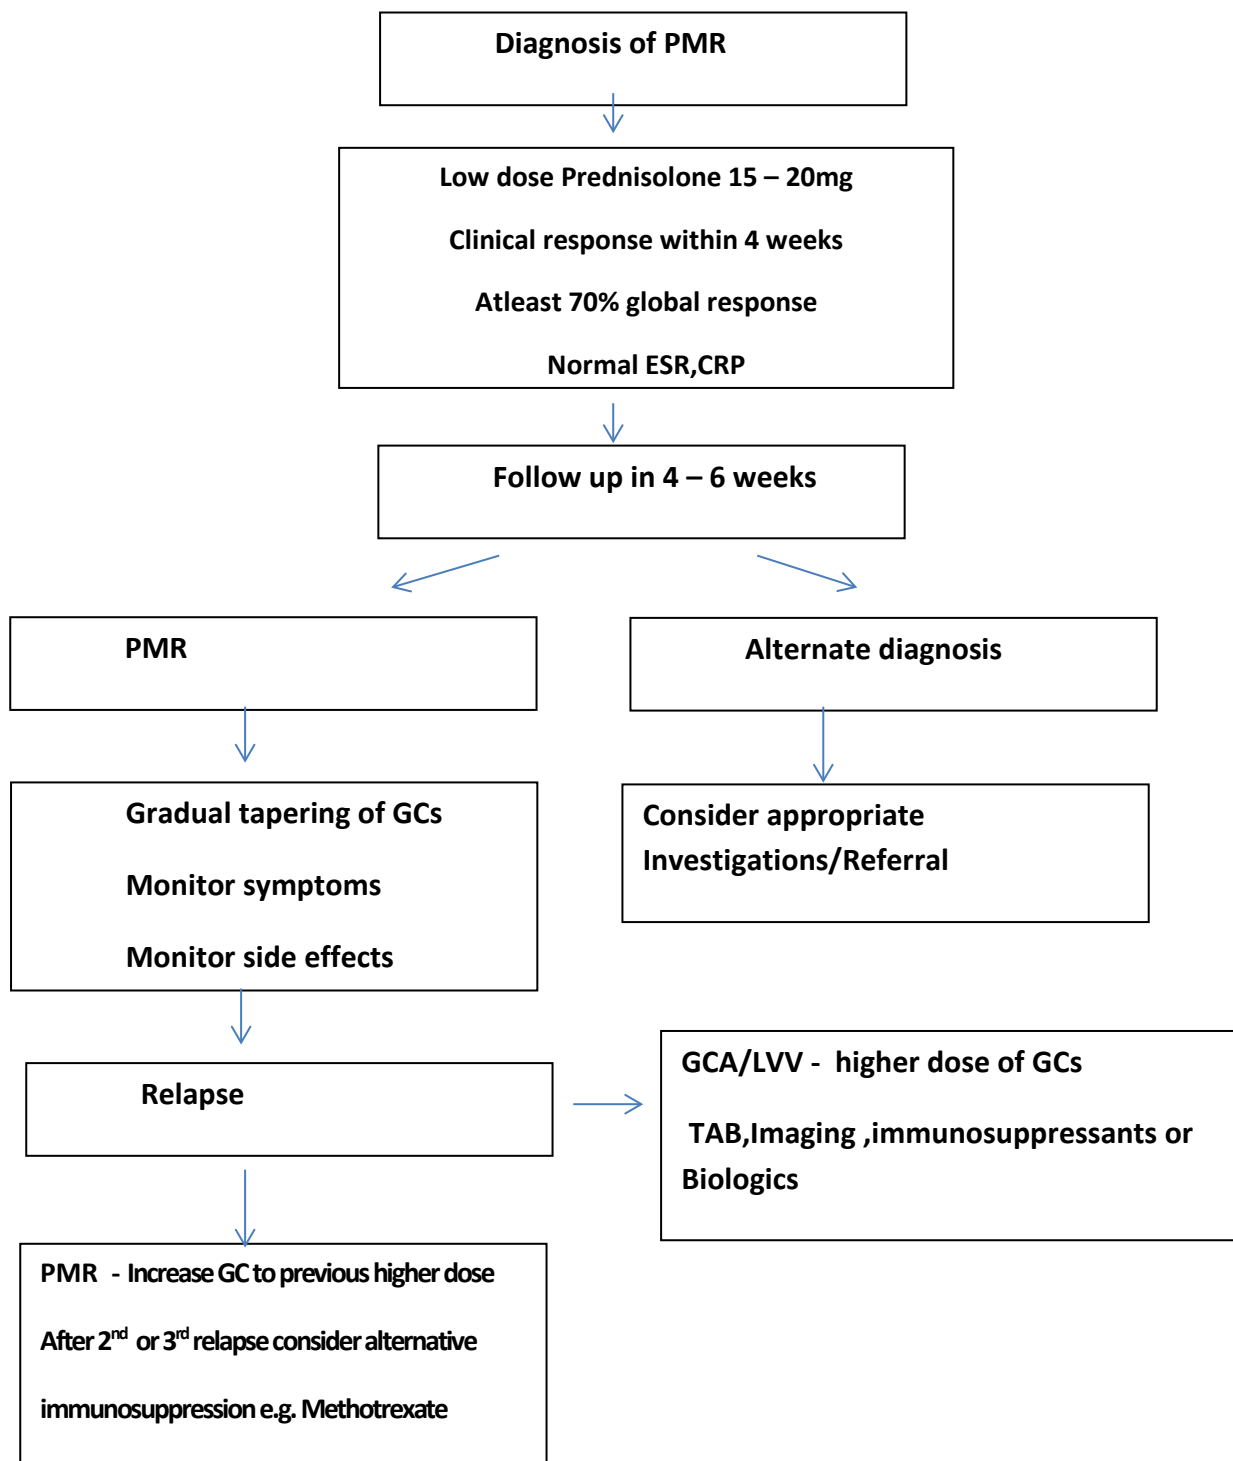

Parkinson's disease may be confused with PMR when muscle stiffness predominates in the shoulder and pelvic girdles and other clinical features of Parkinson's disease, such as tremor, are less conspicuous. In such cases, the lack of improvement in stiffness during the day and the absence of raised inflammatory markers should cast suspicion on a diagnosis of PMR, while a careful search for subtle signs of neurological involvement can lead to the correct diagnosis.

Drugs —for example, statins can also cause symptoms mimicking PMR. Immune checkpoint inhibitors may induce real arthritis as RA, SpA or ...PMR.

Fibromyalgia can cause muscle pain and a feeling of stiffness aggravated by exposure to cold and heavy physical activity, particularly in the neck and shoulder area, but inflammatory indices are not raised. Physical examination in fibromyalgia typically discloses positive tender points in the absence of synovitis.

Hypothyroidism can cause pain and stiffness in the muscles, including those around the shoulders, and can mimic PMR. However, in hypothyroidism muscle stiffness does not substantially improve as the day goes on. In its most pronounced form (Hoffmann's syndrome), hypothyroid muscle disease can present with muscle pain, stiffness and muscle hypertrophy. The differential diagnosis is generally easy because hypothyroid muscle disease is often associated with other clinical features of hypothyroidism. Laboratory tests show normal inflammatory markers, altered thyroid function and moderately raised creatine kinase levels.

A flow chart based on previous reports of the diagnosis and management of patients presenting with polymyalgia-like symptoms, is shown in figure 5.

8.2 Differential diagnosis of GCA

Every patient with suspected GCA requires a confirmatory diagnostic (histologic or imaging) test. The diagnosis of typical high probability GCA is relatively simple, but can be challenging if it presents with atypical features.

Temporal artery involvement is highly suggestive of GCA, although cases of headache due to temporal artery involvement in the presence of primary systemic necrotising vasculitides such as polyarteritis nodosa or granulomatosis with polyangiitis or cases of amyloidosis have been described. In such cases, TAB is invaluable in securing the correct diagnosis.

New-onset headache is also one of the most common presenting symptoms of primary central nervous system vasculitis. However, cerebral vasculitis is rare in GCA.

In elderly patients, LV-GCA accounts for about one-sixth of cases of fever of unknown origin. Therefore, vasculitis should be suspected in older patients with fever of unknown origin who have no evidence of infection or neoplasm. A PET-CT in this context may be very valuable to rule in GCA and exclude other serious pathology.

Visual loss, usually due to AION, is a very early, and often the initial, manifestation of GCA. In patients with visual loss, diagnosing GCA is easy in the presence of other clinical manifestations consistent with GCA and the finding of raised acute phase reactants. There are reports of occult GCA where diagnosis is made only after sight loss. In most such cases direct questioning reveals presence of non-specific constitutional and MSK symptoms that can be missed in the elderly. In these cases, the diagnosis usually rests on the demonstration of raised acute phase reactants and a confirmatory imaging or TA biopsy. AION should be differentiated from non-arteritic AION (NAION). NAION is commoner than AION, occurs almost exclusively in Caucasians at a younger age than GCA and is characterised by a sudden visual loss in one eye without premonitory signs. Contralateral eye involvement in NAION can occur, but is less common than in AION. Fundoscopy usually shows hyperaemic (less often pale) oedema of the optic disc with a small cap size. Systemic manifestations are not associated with NAION. Optical coherence tomography with angiogram is a research tool that may help differentiate the two disorders. Finally, cases of carotid occlusion mimicking GCA have also been described (González-Gay et al, 1998d).

9 Treatment of PMR and GCA

9.1 Treatment of PMR

Glucocorticoids remain to date the cornerstone of treatment for PMR and GCA (Gonzalez-Gay et al, 2006; Hernandez-Rodriguez et al, 2009; Gonzalez-Gay et al, 2010a; Gonzalez-Gay et al, 2010b; Kermani and Warrington, 2013*; Matteson et al, 2016). Non-steroidal anti-inflammatory drugs are of little value in the management of PMR. Treatment guidelines have been published by the British Society of rheumatology (BSR) and a collaborative initiative of the European League Against rheumatism (EULAR) and the American college of Rheumatology (Dejaco C 2015).

Low dose Glucocorticoids are the recommended standard treatment for PMR.

In PMR, an initial dose of 10–20 mg of prednisone or prednisone-equivalent per day is sufficient in the vast majority of cases to control the inflammatory symptoms. Starting doses of prednisone or an equivalent of >10 mg/day have been shown to be associated with fewer relapses and shorter treatment duration, while starting doses of >15 mg/day have been linked to a higher cumulative prednisone dose and more glucocorticoid-related adverse events. Most patients respond to glucocorticoid therapy within a few days, generally in less than 1 week, with complete or nearly complete resolution of their pain and stiffness, although very occasionally a patient may require a prednisone dose of up to 30 mg daily to attain disease control. A rapid response in 24–72 h can help to confirm the diagnosis.

Lack of clinical improvement after treatment with prednisone 20 mg daily for a week should prompt the physician to question the diagnosis of PMR and consider other diagnoses. Higher glucocorticoid dosages may be effective in inflammatory conditions other than PMR and thus are best avoided as they may delay the correct diagnosis. Lack of complete response as well as atypical clinical features, such as peripheral joint disease, pain with little stiffness and muscle weakness, should prompt consideration of alternative diagnoses.

Higher doses of prednisone are not likely to provide an additional benefit in isolated PMR and have, in fact, been linked both to more frequent glucocorticoid-related adverse reactions and to an increased risk of relapse. In addition, glucocorticoid pulse therapy (intravenous methylprednisolone 250 mg daily for 3 days) did not induce clinical remission or reduce the cumulative glucocorticoid dose and is thus not recommended (Cimmino et al, 2004). EULAR/ACR recommend tapering to 10mg/day within 4 – 8 weeks followed by a taper by 1mg every 4 weeks assuming patients are in remission.

Fast tapering schemes are best avoided as they substantially increase the risk of disease relapse.

Persistently raised concentrations of CRP and IL-6 have also been associated with a relapsing disease course in PMR. However, an increase in inflammatory markers in the absence of clinical symptoms does not in itself mandate an increase in the dose of glucocorticoid. It is important to treat the patient's symptoms and not rely exclusively on inflammatory markers to guide treatment. Persistence of a raised ESR may be indicative of an additional condition.

In general, a treatment course of 1–2 years is often required, but some patients might need to continue receiving glucocorticoid (mostly at low doses) for several years and even indefinitely, often maintained on 2.5–5 mg of prednisone daily. The dose should be kept as low as possible to treat the symptoms in remission.

If relapse occurs (Myklebust and Gran, 2001; Kremers et al, 2005), it may be necessary to increase the steroid dosage to the previously effective level. However, it is important to keep glucocorticoid toxicity as low as possible and to implement osteoporosis prevention methods. Management of comorbidities, including

prophylaxis for cardiovascular disease, is also necessary. Blood pressure, blood lipids and blood glucose should be assessed and the patient screened for osteoporosis. Prophylaxis for osteoporosis should be started within the first few weeks of treatment.

Glucocorticoids are notorious for adverse events, which are largely related to the cumulative dose. In a study of 124 patients with PMR treated with glucocorticoid alone, 65% had at least one glucocorticoid-related adverse event. High risk phenotypes (treatment unresponsive at 4 weeks, older age at diagnosis, females, high inflammatory markers, risks for GCs adverse events) may benefit from early initiation of adjunctive immunosuppressants (Dejaco C 2015)

Some attempts have been made to investigate other drugs as glucocorticoid-sparing agents. Two randomised controlled trials (RCTs) have investigated the efficacy of methotrexate (MTX) in PMR (Van der Veen et al, 1996; Caporali et al, 2004). In one of these RCTs, 40 patients with PMR (six of whom also had symptoms of GCA) were randomised to prednisone 20 mg daily with a rapid tapering scheme and either MTX 7.5 mg by mouth weekly or placebo. Twenty-one patients were followed up for at least 2 years, or 1 year after treatment withdrawal. There was no difference between the study arms for time to remission, number of relapses or cumulative glucocorticoid dose. In a subsequent RCT, 62 patients with PMR were treated with an initial dose of prednisone 25 mg daily, which was tapered within 24 weeks in the absence of flares. Thirty patients received placebo and 32 received MTX 10 mg by mouth weekly for 48 weeks. This study showed significant differences in the outcome measures between the two study groups: (a) 28 of 32 patients in the MTX group and 16 of 30 patients in the placebo group were able to discontinue prednisone at 76 weeks; (b) 15 of 32 patients in the MTX group and 22 of 30 patients in the placebo group had at least one flare-up by the end of follow-up; and (c) the median prednisone dose was lower (2.1 g) in the MTX group than that (2.97 g) in the placebo group. Despite these differences, the rates and severity of adverse events were similar in both study arms. These results suggest that MTX may be effective in reducing the incidence of relapses and the amount of prednisone needed to maintain remission when the drug is started at disease onset and given for at least 1 year at a dose of at least 10 mg a week. However, the reduction in the cumulative glucocorticoid dose achieved in this trial was not paralleled by a decreased frequency and severity of glucocorticoid-related adverse events. It remains to be established whether MTX at higher doses might prove more effective or act more rapidly. It is also unclear how effective MTX would be when given in patients with longstanding disease refractory to glucocorticoid.

Small retrospective series have suggested possible efficacy of leflunomide [Adizie T 2012, Diamantopolos AP 2013]. In a series of 14 patients with refractory PMR, partial (GC reduction) and complete (GC discontinuation) responses were observed in 9 and 4 patients respectively with addition of LEF [Adizie T 2012]. In another series of 12 patients with PMR, 34% patients were able to reduce GC doses with improvement in

CRP levels at 10.5 months [Diamantopoulos AP 2013]. RCTs are in setup to explore the role of this medication in PMR and GCA.

A number of studies have reported the use of tumour necrosis factor α (TNF α) blocking agents in PMR (Catanoso et al, 2007). In a pilot study, four patients with longstanding, relapsing PMR and glucocorticoid-related adverse events who were unable to decrease their prednisone dose below 7.5–12.5 mg daily were treated with the anti-TNF α monoclonal antibody infliximab (3 mg/kg intravenously) at baseline and after 2 and 6 weeks (three infusions only) (Salvarani et al, 2003). Three of the four patients were able to stop taking prednisone without experiencing disease relapses. Similarly, the TNF α receptor Fc-fusion protein etanercept 25 mg given subcutaneously twice weekly showed efficacy in six patients with longstanding PMR taking prednisone 7.5–10 mg daily. In one patient, glucocorticoids could be withdrawn, while in five the prednisone dose could be reduced to 2.5 mg daily without any resulting flare. There were two cases of urinary tract infection and one case of influenza.

In contrast to these encouraging results in patients with longstanding PMR, infliximab has not proved more effective than placebo in an RCT of patients with newly diagnosed PMR (Salvarani et al, 2007). In that study, 51 patients with newly diagnosed isolated PMR received prednisone 15 mg/day tapered over 16 weeks in the absence of flares. Infusions of placebo or infliximab (3 mg/kg) were given at 0, 2, 6, 14 and 22 weeks. The primary study outcomes were the numbers of patients with a relapse or who were recurrence-free, while secondary outcomes included the number of patients no longer taking prednisone, the number of flares, the duration of prednisone therapy and the cumulative prednisone dose throughout the planned trial duration of 52 weeks. The results of this study showed no significant effect of infliximab on any of the outcome variables at weeks 22 and 52. There was no significant difference in adverse events between the study arms. This trial had a number of limitations, including the relatively low dose of infliximab used, the rapid tapering of prednisone, the small sample size and the short duration of follow-up.

The authors of this RCT concluded that although too small to be definitive, the trial provided evidence that adding infliximab to prednisone for treating newly diagnosed PMR is of no benefit and may be harmful. They emphasised that if there is a benefit, it is unlikely to be large.

A more recent RCT designed to study the effect of etanercept in newly diagnosed, glucocorticoid naive patients with PMR showed that the PMR activity score decreased by 24% in the patients with PMR treated with etanercept, but did not change significantly in the placebo-treated patients (Kreiner and Galbo, 2010)

However in view of all these apparently contradictory results, the EULAR/ACR treatment guidelines do not recommend anti-TNF therapy in PMR

Tocilizumab is efficient in refractory PMR (Hagihara et al, 2010, Seitz et al, 2011; Toussirost et al, 2016.

Devauchelle-Pensec et al, 2015 have demonstrated in an open-label uncontrolled trial (“TENOR study”) that tocilizumab is efficient as a first-line treatment for PMR. Twenty patients with PMR were treated with three tocilizumab intravenous infusions at an initial dose of 8 mg/kg with 4-weeks intervals followed by oral prednisolone. At 12 weeks, the primary end-point of a PMR activity score <10 was achieved in all patients.

The TENOR study has revealed the efficacy for the first time of a treatment other than glucocorticoid in PMR, but the risk: benefit ratio of tocilizumab has to be considered, especially the risk of infections, leukopenia, elevations of liver transaminases, modifications of serum lipid levels and alterations in cholesterol composition.

9.2 Treatment of GCA

As described for PMR, glucocorticoids are also mainstay treatment in GCA (Salvarani et al, 2008b; Gonzalez-Gay et al, 2010a; Gonzalez-Gay et al, 2010b; Masson, 2012*; Matteson et al, 2016, Bienvenu et al, 2016, Dejaco et al, 2015a, Dejaco et al, 2015b, Das, et al, 2015). They are the preferred treatment because of their ability to rapidly control inflammatory symptoms and prevent most ischaemic manifestations, including visual loss.

In patients with GCA, without severe ischaemic complications, an initial dose of prednisone or its equivalent of 40 mg/day (or 0.7 mg/kg) is usually recommended. But in patients with GCA who present with visual ischaemic complications or other severe ischaemic manifestations, such as cerebrovascular accidents or large artery stenosis of the extremities resulting in occlusion (limb claudication) of recent onset, an initial prednisone dose of 60 mg/day is necessary.

The use of glucocorticoids has dramatically decreased the frequency of severe visual ischaemic complications in patients with GCA. Indeed, a decrease in the incidence of permanent visual loss was seen in Olmsted County, Minnesota (USA), where 19% of patients with GCA were blind during the period 1950–1969 compared with 6% during the period 1980–1985.

Data show that it is not the absolute dose but the time from onset of symptoms to first administration of glucocorticoids that is predictive of improvement in visual loss.

Once visual loss is established, the prognosis for significant visual recovery in patients with GCA despite glucocorticoid therapy is poor. Literature review suggests that glucocorticoid therapy should not be delayed under any circumstances in patients with GCA with suspected visual impairment. The efficacy of high-dose oral prednisone is comparable to that of intravenous pulse glucocorticoid therapy.

Apart from visual loss, most GCA symptoms usually begin to improve within 24–72 h after the start of glucocorticoid therapy. Also, normalization of routine laboratory parameters of inflammation (CRP, and then ESR) occurs within 2–4 weeks after starting this treatment. The glucocorticoid dose can then be gradually tapered. Prednisone is generally reduced by 5 mg every 2–4 weeks down to 25 mg. It can then be reduced by 2.5 mg every 2–4 weeks until the dose is 10 mg and later by about 1 mg every month. However, the duration of glucocorticoid therapy in GCA is variable; nearly half of them relapses, may last for 2–4 years, and sometimes cannot be stopped.

There have been contradictory data regarding benefit of IV over oral GCs in this subgroup with visual impairment (Gonzalez – Gay MA 1998, Liu GT 1994,). A study compared an initial high-dose pulse of intravenous methylprednisolone with standard oral glucocorticoid therapy (Mazlumzadeh et al, 2006). The authors carried out a double-blind, placebo-controlled, randomized, prospective clinical trial: a 3-day course of intravenous methylprednisolone pulses (15 mg/kg of ideal body weight/day) in addition to oral prednisone (n = 14) compared with normal intravenous saline infusions plus oral prednisone (n = 13). The initial intravenous pulse of methylprednisolone therapy yielded more rapid glucocorticoid tapering, a lower median dose at each visit and fewer relapses. However, further studies including larger numbers of patients are required to establish the routine use of intravenous pulse methylprednisolone as initial glucocorticoid therapy for the management of GCA.

Adjunctive therapies:

The incidence of GC related side effects is very high and reported to be around 86% over 10 years; therefore alternative Immunosuppressive agents are desperately needed to reduce the GCs burden. Indeed, alternative glucocorticoid-sparing drugs should be considered in patients with GCA with severe glucocorticoid-related side effects and/or in patients who require prolonged glucocorticoid therapy owing to disease relapse. MTX was evaluated in newly diagnosed GCA in three RCTs, which produced discordant results. The first study by Spiera et al compared 12 patients treated with MTX starting at 7.5 mg/week with nine patients treated with a matched placebo (Spiera et al, 2001).

All patients received high-dose glucocorticoid treatment with the dosage tapered according to clinical response, while the dose of MTX or placebo was increased by 2.5 mg/week for disease flare up to 20 mg/week. There were no significant differences at the end of the study between MTX- and placebo-treated patients in the cumulative glucocorticoid dose and number of weeks to taper the glucocorticoids. Side effects did not significantly differ between groups.

The other two randomized clinical trials of the use of MTX in GCA included larger numbers of patients but had contradictory results. Jover et al studied 42 patients from Madrid (Spain) (Jover et al, 2001). A single weekly dose of oral MTX (10 mg) or placebo was started on diagnosis, maintained throughout the treatment period

and discontinued after 24 months of follow-up if clinical signs of disease activity were absent. All patients started treatment with oral prednisone 60 mg/day during the first 2 weeks and then gradually tapered. This 24-month placebo controlled trial showed a significant reduction in the rate of relapse of GCA and mean prednisone dose in MTX-treated patients compared with a placebo group, but no differences in the severity of the disease and the side effects.

Hoffman et al performed multicentre randomized clinical trial of MTX in GCA (Hoffman et al, 2002). In this study the initial treatment was prednisone 1 mg/kg/ day (≤ 60 mg every day), plus 0.15 mg/kg/week MTX (increased to 0.25 mg/kg/week, for a maximum weekly dosage of 15 mg) or placebo. The median dose of MTX was 15 mg/week. Unfortunately, this multicentre study did not support the adjunctive use of MTX to control disease activity or to decrease the cumulative dose and toxicity of glucocorticoids in patients with GCA.

The data from the above three RCTs were the subject of a formal meta-analysis, which showed that adjunctive MTX treatment at 7.5–15 mg per week reduced the risk of a first relapse in GCA by 35%, and of a second relapse by 51% (Mahr et al, 2007). Adjunctive MTX treatment also reduced the cumulative glucocorticoid dose. However, the incidence of glucocorticoid-related side effects was similar in both groups. Furthermore, the clinical effect of MTX fully appeared only after 24–36 weeks.

Therefore, while MTX appears to be effective in GCA, it does not act rapidly. As a result, MTX cannot be recommended as a replacement for glucocorticoids at disease onset. Equally important, adjunctive MTX therapy has not been shown to decrease the incidence of glucocorticoid-related complications, which raises the question of the real clinical significance of adjunct MTX therapy in GCA. It is unclear whether higher-dose MTX (20–25 mg/week) would be more effective or act more rapidly, or how effective MTX would be when given to patients with longstanding, glucocorticoid-refractory GCA.

Azathioprine given at 150 mg daily has been assessed in a 52-week, double-blind placebo-controlled trial in 31 patients with PMR, GCA or both (De Silva and Hazleman, 1986). All patients had been receiving stable prednisolone for at least 3 months before being enrolled. The results showed a statistically significant difference in the mean prednisolone dose (1.9 ± 0.84 mg in the azathioprine arm vs 4.2 ± 0.58 mg in the placebo arm), but only at week 52. However this study recruited both PMR and GCA patients, therefore it is difficult to ascertain whether there was a true effect in GCA.

Leflunomide

Two case series of leflunomide as a GC sparing in GCA have been published with nine and 12 patients (Adizie T 2012, Diamantopoulos AP 2013). Each study showed improvement in prednisolone dose tapering, suggesting that leflunomide may have a role as steroid sparing.

TNF α inhibitors have also been used in some patients with GCA. The rationale for their use is based on evidence of TNF α synthesis in inflamed temporal arteries and demonstration of raised circulating TNF α levels in patients with GCA.

Three RCTs of TNF- α antagonists failed to show efficacy in GCA [Hoffman GS 2007, Martinez-Taboada VM 2008, Seror R 2014]. The studies used different anti-TNF therapies (ETN, IFX and adalimumab (ADA)), different populations of patients (newly diagnosed in 2 studies) and had different endpoints which limits their interpretability. In a multicentre RCT of 44 patients with new GCA randomized to GCs and IFX (5 mg/kg, 28 patients) or GCs and placebo (16 patients), relapse free survival at 22 weeks (primary outcome) was similar in both groups (43% IFX versus 50% placebo, $p=0.65$) (Hoffman 2007). Infectious AEs were observed in 47% in the IFX group compared to 23% in the placebo arm with serious infections in 11% of the IFX patients and 6% of the patients on placebo. In another RCT of only 17 patients with biopsy-proven GCA randomized to ETN 25 mg twice weekly (8 subjects) or placebo (9 subjects), GC discontinuation at 12 months (primary outcome) was met in 50% in the ETN arm compared to 22% in placebo arm (NS) [Martinez Taboada 2008]. A RCT using ADA 40 mg every other week (34 patients) or placebo (36 patients) for 10 weeks in patients with newly diagnosed GCA, found no differences in remission on less than 0.1 mg/kg of prednisone at week 26 (59% ADA arm and 50% placebo arm, $p=0.46$) [Seror R 2014]. Serious AE occurred in 5 patients (3 serious infections) on ADA and 17 patients (5 serious infections) on placebo.

Anti-TNF therapies have not shown benefit in GCA. The draft BSR GCA guidelines do not advocate the use of anti-TNF blockade in GCA (manuscript in preparation).

The treatment option for patients whose disease is resistant to glucocorticoids (GCs) and who have an insufficient response to standard GCs for induction of remission, and GC-dependent cases after successful induction of remission, remains an open question, with the need for other prospective trials (Kötter et al, 2012*). The new prospects for PMR and GCA treatment include fairly convincing evidence for a role for IL-6 in both PMR and GCA. Interleukin – 6 induces acute phase responses and has a central role in the pathogenesis of GCA (Dasgupta B 1990, Garcia – Martinze A 2010, Weyand CM 2000, Weyand CM 2011). The IL-6 blocker tocilizumab (TCZ) (a humanized anti-IL-6 receptor monoclonal antibody) has been reported to be effective in several published case series with large vessel vasculitis (Unizony et al, 2012, Loricera et al, 2015, Regent et al, 2016).

A single-centre phase II randomized placebo-controlled study has demonstrated the efficiency of TCZ in the induction and maintenance of remission in patients with 23 newly diagnosed GCA (Villiger et al, 2016). GCs were tapered and discontinued using a standardized protocol. The primary outcome of complete remission at a prednisolone dose of 0.1 mg/kg/day at week 12 and was met in 85% of patients in the TCZ group compared to 40% in the placebo group ($p=0.03$). Relapse-free survival at week 52 was observed in 85% patients in the TCZ group compared to 20% with placebo ($p=0.001$). Adverse effects were observed in 15 patients (75%) in the

TCZ group (26 events; 7 serious adverse effects) and 7 patients (70%) in the placebo group (23 events; 10 serious adverse effects). Infectious were observed in 10 patients in the TCZ group compared to 1 in the placebo arm.

In a recent randomized, double blind, placebo controlled, phase 3 trial, the Giant cell arteritis Actemra (GiACTA) trial showed beneficial results with Tocilizumab (J Stone et al 2017).

251 patients with newly diagnosed or relapsing disease were randomized 1:1:2:1 to 26 week prednisone taper and placebo, 52 week prednisone taper and placebo, 26 week prednisone taper and TCZ 162 mg subcutaneously weekly or 26 week prednisone taper and TCZ 162 mg subcutaneously every other week. Primary endpoint was the proportion of patients in sustained remission (week 12 to week 52) in the TCZ group compared to the 26 week prednisone and placebo group (significance level set to 0.005) and the key secondary outcome of sustained remission was assessed against the 52 week GC taper group . Sustained remission occurred in 56.0% of patients in the TCZ-weekly arm and 53.1% in the TCZ-every-other-week arm, compared with 14.0% in placebo-26-week prednisone taper and 17.6% in placebo-52-week prednisone taper (P<0.001 for comparisons of either active treatment to placebo at each time point). The cumulative median prednisone dose over 52 weeks was 1862 mg in each of the TCZ groups compared with 3296 mg in the placebo-26-week group (p<0.0001) and 3818 mg in the placebo-52-week group (P <0.0003). Any adverse effects was observed in the majority of patients as follows: 98.8% weekly TCZ group, 95.9% every other week TCZ group, 96% of the 26-week prednisone arm and 92.2% of the 52-week prednisone arm .Serious adverse effects were seen with 15.0% of TCZ-weekly, 14.3% of TCZ-every-other-week, 22.0% of placebo-26-week taper, and 25.5% of placebo-52-week taper patients. Serious infectious were observed in 7% and 4.1% of the weekly and every other week TCZ arms respectively, and, 4% and 11.8% of the 26 week and 52 week prednisone arms respectively. Long-term follow-up is required regarding safety and sustained remission.

Another large phase III, randomized, placebo-controlled trial evaluating a different IL-6 antagonist, sirukumab is currently under way (ClinicalTrials.gov identifier NCT02531633).

Activated T-cells have also been implicated in the pathogenesis of GCA. In a multicentre, randomized, study, 49 patients were treated with prednisone and abatacept (ABA) (10 mg/kg intravenously on days 1, 15, 29 and week 8) [Langford CA 2017]. At 12 weeks, 41 patients who were in remission were randomized to ABA (intravenously monthly, N=20) or placebo (N=21). Prednisone was tapered by using a standardized protocol. Relapse-free survival at 12 months was 48% in the ABA group compared to 31% in the placebo group (p=0.049). Median duration of remission was also longer for the treatment group (9.9 months) compared to placebo group (3.9 months) (p=0.023). Overall, adverse effects were observed in 35 patients (129 events; 23 serious adverse effects). This included 33 infections; 2 of which required hospitalization .There were no differences in frequency of AE between the two arms. The results of this study are promising.

IL-12 and IL-23 in the Th1 and Th17 responses are also recognized in the pathogenesis of GCA, therefore ustekinumab, a monoclonal antibody against IL-12/23p40, was studied in an open-label study of 14 patients with GCA with a median prednisolone dose of 20 mg/day and median of 2 relapses. 86% of the patients had also failed other adjunctive immunosuppressive therapy. After a median follow-up of 13.5 months (range 7-26 months), none of the 14 patients experienced a relapse, prednisolone was lowered to median 5 mg/day and 4 patients (29%) were able to discontinue prednisolone completely. There were 6 adverse effects; 4 of which were infectious (Conway R 2016)

Aspirin may be considered for the adjuvant treatment of patients with GCA. Thus, two retrospective studies suggested that low-dose aspirin may prevent ischaemic complications due to GCA (Nesher et al, 2004; Lee et al, 2006). In one study, only 8% of the aspirin-treated patients presented with cranial ischaemic complications, compared with 29% of the non-aspirin-treated patients. Similarly, after the start of glucocorticoid treatment, cranial ischaemic complications developed in only 3% of the aspirin-treated patients compared with 13% of the patients treated with glucocorticoid alone. In another retrospective study, 16.2% patients receiving antiplatelet or anticoagulant therapy had a GCA-related ischaemic event compared with 48.0% not receiving such treatment. Therefore, according to these results, antiplatelet therapy started before GCA diagnosis may reduce the risk of severe ischaemic events in patients with GCA. Thus, in view of the above-mentioned data, we recommend the prescription of aspirin (75–125 mg/day) in patients with GCA, although there is no formal evidence of efficiency from other studies (Berger et al, 2009; Salvarani et al, 2009) and RCTs are lacking (Mollan et al, 2014).

Bone protection treatment should be considered in patients with GCA as long-term glucocorticoid therapy induces bone loss. Therapeutic agents aimed at restoring balanced bone cell activity, either by directly decreasing the rate of osteoblast apoptosis (such as cyclical parathyroid hormone) or by increasing the rate of osteoclast apoptosis (such as bisphosphonates), are potentially useful in the management of people with GCA or PMR receiving long-term glucocorticoid therapy.

10 Course and mortality in GCA and PMR

Approaches to rapid diagnosis and treatment have recently been shown to reduce the incidence of sight loss associated with GCA. In one study, there was a reduction in incidence of blindness from 37% in the historical cohort to 9% following introduction of fast track pathway (Patil P 2015) Similarly implementation of an outpatient fast track ultrasound GCA clinic in Norway resulted in significant reduction in permanent visual impairment in GCA patients compared with those treated conventionally (RR0.12, 95%CI: 0.01 – 0.97) with a

reduction in inpatient days (Diamantopoulos 2016). These studies suggest that early diagnosis and intervention in GCA management can reduce permanent visual loss.

Frequencies of severe infections and rates of infection-related mortality are increased during the first year after the diagnosis of GCA (Schmidt et al, 2016). The risk of infection in this multicentre, prospective, double-cohort study increases in GCA patients with older age or in the presence of diabetes, or if the average dose of corticosteroids is over > 10 mg/day after twelve months of treatment.

Relapses are common in GCA and PMR (Gonzalez-Gay et al, 1999c; Salvarani et al, 2005b; Martinez-Lado et al, 2011). The rate of relapse is higher in those with fast tapering of the steroids. However, disease flares can occur throughout the course of glucocorticoid therapy and be independent of the glucocorticoid regimen. Typical flares of the disease are associated with raised ESR and CRP as well as with disease-related manifestations. A population-based study confirmed a high frequency (41%) of relapses or recurrences in patients with biopsy-proven GCA. Those patients with GCA who had relapses or recurrences did not show clinical differences in comparison with the remaining patients with biopsy-proven GCA. However, the total duration of glucocorticoid therapy was significantly longer in the patients who had relapses or recurrences of the disease. The median dose of prednisone and the median duration of glucocorticoid treatment at the time of the first relapse were 5 mg/day and 16 months, respectively. Headache (52%) was the most common feature at the time of first relapse of GCA. PMR manifestations occurred in 30% of the patients with biopsy-proven GCA at the time of first relapse, but none developed visual loss. The presence of anaemia (haemoglobin <12 g/dL) at the time of disease diagnosis was the best predictor of relapse or recurrence of GCA.

Despite the increased risk of irreversible visual loss and the increased frequency of aortic aneurysmal disease in patients with GCA, most long-term survival studies have shown no excess mortality in GCA or PMR (Delecoeuillerie et al, 1988; Schaufelberger et al, 1995; Matteson et al, 1996; Gonzalez-Gay et al, 1997a; Bahlas et al, 1998; Gran et al, 2001; Gonzalez-Gay et al, 2007a).

As with many other rare diseases, it is important to understand the natural history of the disease. Few longitudinal prospective studies, French GRACG, Slovenian and Spanish prospective cohorts have provided valuable information regarding clinical features, risk of relapse and complications. However there is an unmet need to study further biomarkers, histopathological diagnosis, prognostic markers, standardized data collection and patient reported outcomes.

SUMMARY POINTS

- Polymyalgia rheumatica (PMR) is an inflammatory disorder characterised by pain, aching and morning stiffness in the shoulder girdle and often in the pelvic girdle and neck. Recent classification criteria has provided differentiation of PMR from several possible mimics of this disease and a stepwise assessment which includes inclusion and exclusion criteria and use of low-dose steroids. Examination should also include evaluation of the temporal arteries, peripheral pulses and auscultation for bruits. If vascular abnormalities are present, evaluation for GCA should be undertaken.
- Giant cell arteritis (GCA) is a vasculitis mainly involving the large and medium arteries.
- GCA and PMR are common and often overlapping conditions in elderly Western populations.
- A genetic component—in particular, in patients with biopsy-proven GCA, has been reported.
- GCA is an antigen-driven disease with local T cell and macrophage activation in the vessel wall, with proinflammatory cytokines playing an important role.
- The clinical features of GCA, chiefly headache, are mainly due to involvement of the cranial arteries.
- Permanent visual loss, generally due to anterior ischaemic optic neuropathy, is the most feared complication of GCA.
- Aortic arch syndrome, aortitis, which involves the thoracic aorta more often than the abdominal aorta, is also described, with risk of stenosis, dissection and or aneurysm formation. This has also been seen in the vertebral arteries in patients with GCA.
- Vertebral and basilar artery lesions can be responsible for fatal cerebrovascular events.
- The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are generally raised in most patients with GCA and PMR; however, some cases with low ESR have been reported.
- A temporal artery biopsy remains the 'gold standard' to secure the diagnosis of GCA.
- High-resolution colour Doppler ultrasonography has gained widespread acceptance as a diagnostic tool in GCA.
- Positron emission tomography with ¹⁸F-fluorodeoxyglucose (FDG/PET) can be used to secure the diagnosis of large vessel GCA.
- Glucocorticoids remain the cornerstone of treatment in PMR and GCA.
- In PMR, an initial dose of 10–20 mg/day of prednisone or its equivalent is adequate in the vast majority of cases to control the inflammatory symptoms.
- In patients with GCA, without complicated lesions, an initial dose of prednisone or its equivalent of 40 mg/day for 3–4 weeks is usually recommended.
- In patients with severe ischaemic lesions, an initial dose of prednisone or its equivalent of 60 mg/day as a single or divided dose for 3–4 weeks is usually recommended.
- In general, treatment for 1–2 years is often required, but some patients may need (mostly at low doses) for several years or more.
- Relapses (flares) are not uncommon in GCA and PMR. Alternative glucocorticoid-sparing drugs—in particular, methotrexate, should be considered in patients with GCA with severe glucocorticoid-related side effects and/or in patients who require prolonged glucocorticoid therapy owing to disease relapse.

Future Research:

1. There remains a need for additional tests or biomarkers, especially where or when the diagnosis is not clear-cut.
2. The new EULAR/ACR classification criteria will facilitate uniform entry into clinical trials of novel therapies which are so urgently required for the condition. There appears to be an overlap with GCA and large-vessel vasculitis as well as inflammatory arthritis.
3. Bursal Biopsy studies are in progress
4. Development of treatment protocols and preventive strategy

IN-DEPTH DISCUSSION I

Giant cell arteritis with large-vessel involvement

Involvement of large vessels (the aorta and its main branches) is not uncommon in giant cell arteritis (GCA), but may easily remain unrecognized in the early stages because it is often per se asymptomatic until vascular complications become manifest. Inflammatory markers do not reliably discriminate between GCA with and without large-vessel vasculitis, while large-vessel biopsy is virtually unfeasible. Therefore, one has to rely on imaging studies to secure a precocious diagnosis.

The earliest lesions of large-vessel GCA are thought to consist of inflammatory cell infiltration, oedema, and thickening of the vessel wall without changes in vessel lumen. Angiography can visualize the vessel lumen but not the vessel wall; therefore it is not helpful to make an early diagnosis. Instead, Colour-Doppler sonography (CDS), computerized tomography (CT) and magnetic resonance (MR) complemented by angiography are able to depict both the vessel wall and the lumen, and may thus reveal early signs (mural thickening and oedema of the vessel wall) of large-vessel vasculitis. F-18 Fluorodeoxyglucose (FDG) positron emission tomography (PET) cannot reliably delineate the vessel wall, but is very sensitive in revealing active inflammation in the affected vessels.¹ The EULAR recommendations for the management of large vessel vasculitis include the use of PET, together with MRI, for diagnosing large-vessel vasculitis.² However, the absence of standardized methods for interpreting the images constitutes a limitation of PET.

Increased vascular FDG uptake has been observed in 83% of 35 patients with newly diagnosed, untreated GCA.³ The subclavian arteries were most commonly affected (74%), but increased uptake was also noted in the aorta (>50%) and to a lesser extent in the axillary, carotid, iliac and femoral arteries.

In another study on (mostly untreated) 176 patients with new-onset GCA, CDS of the subclavian, axillary, and proximal brachial arteries showed in 53 (30%) patients a long, homogeneous wall swelling, consistent with active vasculitis.⁴

In a more recent study CDS pattern suggestive of vessel wall inflammation was observed in 21 of the 38 patients with GCA (55%).⁵ CDS signs of large vessel vasculitis (LVV) were found in vessel regions of both upper and lower limb vessels. 5 Follow-up DS was performed 6 months after the baseline examination in 9 of the 12 patients with LVV and showed the persistence of most findings despite normalized signs of systemic inflammation ⁵.

The higher prevalence at diagnosis of large-vessel disease found using PET compared to CDS may be related to the very high sensitivity of PET in detecting vessel inflammation as well as to its capacity to visualize arterial segments (such as the thoracic and abdominal aorta), which are not, or only limitedly accessible to CDS.

While large-vessel inflammation has been shown to occur precociously in the course of GCA, vascular complications are usually fairly late events. ^{6,7} In a retrospective cohort study of 168 GCA patients followed up for a mean of 7.6 years, 46 (27%) cases presented with large-vessel complications.⁶ In this series, aortic

aneurysm, dissection, or both occurred in 30 (18%) cases, while large-artery stenosis was found in 21 (13%) patients.⁶ The mean time from the diagnosis of GCA to the occurrence of complications was 5, 6.3 and 1.1 years for thoracic aorta involvement, abdominal aorta involvement, and large-vessel stenoses, respectively. Of those patients who had aortic disease, 18 (11%) had thoracic aorta and 16 (10%) abdominal aorta involvement. Dissection occurred in 9 (5%) of patients with thoracic aortitis, but only in one patient with abdominal aortitis. Thoracic aorta dissection was fatal in 7 (4%) patients.⁶ Of note, simultaneous involvement of the thoracic and abdominal aorta as well as of aneurysms and stenoses was very rare. Large-vessel stenoses were found to affect 21 (13%) of patients; only one patient had lower-limb involvement.

Other studies have confirmed overall similar incidence rates per patient/year of large-vessel complications.^{7,8} According to one of these studies the risk of developing an aneurysm of the thoracic and of the abdominal aorta was 17 and 2.4 times higher, respectively, in patients with GCA than in non-diseased controls.⁸

However, these studies were retrospective and there was not a standardized evaluation process to assess for the presence of either aortic aneurysm or large-artery stenosis in GCA patients, which can have led to under ascertainment of subclinical cases. In a more recent prospective study including 54 GCA patients with a median follow-up of 5.4 years, 22% of cases were found to have aortic aneurysms using a protocol which included a chest radiograph, an abdominal ultrasonography scan and a CT scan if any complication was suspect.⁹

GCA patients with large-vessel involvement may only present with systemic symptoms such as fever, constitutional syndrome, and laboratory evidence of inflammation.¹⁰ Pain in the back or lower back, as well as carotidynia, are inconsistent symptoms. Large vessel stenosis can lead to ischemic manifestations such as claudication of an extremity with an arterial bruit, a blood pressure difference between the two sides, decreased or absent pulses, and Raynaud's phenomenon. It is important to emphasize that headache, visual loss, and jaw claudication occur less commonly in GCA patients with large-vessel involvement than in those presenting with classical cranial GCA.¹¹ Temporal artery biopsy is also less frequently (42% of cases) positive compared to classic cranial GCA.¹¹

Treatment of large-vessel GCA is based on corticosteroids given with the same regimen used in GCA without cranial ischemic manifestation. Symptoms and findings related to arterial stenoses usually respond favourably to corticosteroids, but in selected cases interventional vascular procedures may be required. Patients with aortic aneurysms should be managed similarly to patients with non-arthritic aneurysms.

Vigilant monitoring is required to capture early manifestations of large-vessel arteritis, since large-vessel arteritis may develop at any time in the disease course.¹² ESR and C-reactive protein should be monitored regularly, while chest X-rays and CDS of the aortic arch, of the supra-aortic vessels, and of the abdominal aorta should be done yearly. If large-vessel vasculitis is strongly suspected, MR, CT and/or PET should also be

performed. In patients with established large-vessel arteritis, response to therapy should be assessed by serial measurements of inflammatory markers and by the appropriate imaging techniques.

CDS, MR and CT may be used to monitor stenoses and aneurysms, with the caveat that mural thickening and oedema may persist for long periods of time despite attainment of remission.¹ PET may be more specific to reveal ongoing inflammation. However, inflammatory signs on imaging and PET studies do not necessarily portend the development of new lesions, while apparently inactive vessel segments may subsequently develop complications.¹ Moreover, PET findings shows weak correlations with clinical and laboratory criteria of disease activity and with MRI findings. Thus, PET seems to be no value in the follow-up of GCA patients.

Image 1. Increased (grade 3 on a 0-3 scale) F-18 fluorodeoxyglucose (F-18FDG) uptake on a positron emission tomography (PET) scan of a patient with large-vessel vasculitis involving the thoracic aorta. This finding is highly specific for active vasculitis.

IN-DEPTH DISCUSSION II

GCA and sight loss

‘How do you prevent a stroke in the eye’ – Way Forward.

Headache was identified as an important differentiating feature in the 1990 ACR Classification criteria for GCA. Unfortunately, these criteria have been misused as diagnostic criteria, leading to the mistaken widespread understanding of GCA as primarily a 'headache disease' omitting key constitutional, polymyalgic and major organ threatening features such as jaw pain, visual symptoms and sight loss and large vessel vasculitis. Loss of sight occurs in about 15 – 35 % of patients with GCA and is the most feared complication in GCA (1).

Sight loss in at least one eye still occurs in 15–20% of the cases, because of anterior ischemic optic neuropathy or, less commonly, due to central retinal artery occlusion or ischemic retrobulbar neuropathy (2). In untreated patients with unilateral visual loss, involvement of the contralateral eye may occur, 1–10 days after the initial event, in up to one third of the cases. Irreversible sight loss almost always occurs prior to glucocorticoid therapy. Unfortunately, established sight loss is most often irreversible (2). Sight loss can be preceded by non-specific constitutional symptoms, often missed in the very elderly, and can therefore be the presenting symptom of GCA. Visual impairment can be preceded by diplopia, blurred vision amaurosis fugax, and other ischemic symptoms such as jaw and tongue claudication pain (3). The absence of visual/ischemic symptoms, however, does not preclude the occurrence of visual complications. It has been observed that patients with sight loss reported transient visual symptoms and headache less frequently than patients without visual complications (4). Patients with sight loss are older, as likely in men as in women and more frequently have hypertension and other co-morbidities and a positive temporal artery biopsy. Untreated patients with unilateral visual loss have a 50% risk of blindness in the other eye, usually occurring after a few days (5, 6). Less common ischaemic complications of GCA include TIAs, cerebrovascular strokes, infarction of the tongue and scalp necrosis, Large vessel involvement and aortitis leading to back pain and limb claudication (7).

Patients with GCA related sight loss suffer loss of independence and residential home placement, severe depression, adverse effects from high dose glucocorticoids, severely reduced QALYs because of sight loss. In addition to these personal costs, there are also large direct and indirect healthcare and social costs related to blindness and a major impact on the immediate family.

The key to improving the outcomes of GCA patients is rapid diagnosis and treatment. However, diagnosis is often difficult as the symptoms are similar to many common conditions routinely seen by GP's and Healthcare professionals. The three key areas to address for reducing GCA related sight loss are improved public awareness, improved professional awareness/training and provision of a fast track GCA clinic.

Diagnostic delays and factors have been extensively investigated in strokes, ischaemic heart disease and cancers (8, 9). This led to the development of public health interventions to raise awareness. Similar health care provision is required for GCA to prevent sight loss which can be legitimately regarded as an ischemic 'stroke in the eye'.

In a recent Meta –analysis the importance of understanding the extent of diagnostic delay, and the reasons associated with delay, has been undertaken (10). The mean delay in receiving a diagnosis of GCA ranged from 1.2 (SD 1.6) to 34.7 (34.2) weeks. This meta-analysis demonstrated that those with cranial GCA received a diagnosis after 7.7 weeks (2.7 to 12.8, $P < 0.001$) and those with non-cranial GCA after 17.6 weeks (9.7 to 25.5, $P < 0.001$). They found that even when patients present with distinct cranial symptoms, the delay in finally receiving a GCA diagnosis remains substantial (8 weeks) and is longer still for those with non-cranial symptoms (18 weeks). Such findings are of concern, as previous research has reported that as few as half of GCA patients can experience temporal headaches (11).

On average, patients experience a 9-week delay between the onset of their symptoms and receiving a diagnosis of GCA. Even when the patient has a ‘classical’ cranial presentation, delay remains considerable. In view of the potentially serious consequences of a missed GCA diagnosis, a reduction in diagnostic delay would be beneficial and could result in overall cost savings for healthcare systems (12)

This meta- analysis provides a new evidence-based benchmark of diagnostic delay of GCA against which future efforts to reduce this problem can be measured and supports the need for improved public awareness and fast-track diagnostic pathways.

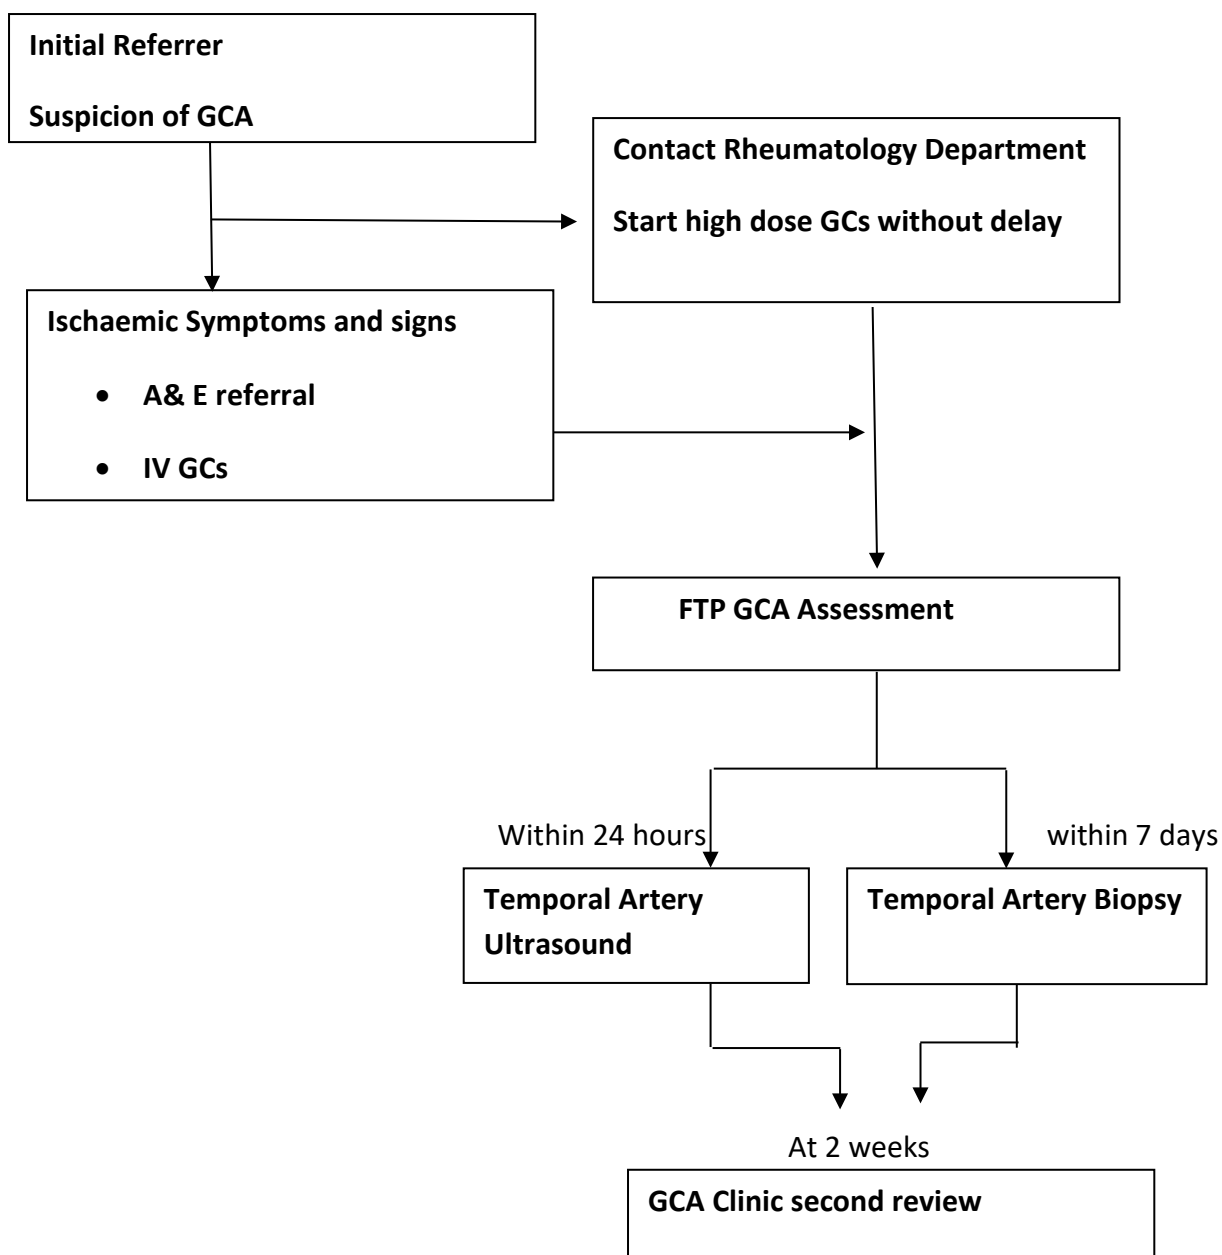

Patients who already have sight loss at the time of diagnosis, have a poorer prognosis and may even have increased mortality. Most guidelines recommend oral prednisone 40 – 60 mg, once daily with the higher dose used in patients with ischaemic symptoms (13). In primary care practice a dose of 60 mg daily should be used in most patients with suspected GCA and if necessary this can be adjusted once the patient has been assessed in secondary care. Improvement in symptoms often begins within hours to days after commencing GCs, with a median time to initial response to an average initial dose of 60 mg/day is 8 days (14).

The proven ability of timely administration of GCs to prevent blindness in GCA is a yardstick against which any other treatment must be measured. While awaiting development of safer therapies we should concentrate efforts in reducing ‘symptom to steroid’ time. A fast track pathway for management of GCA is one such example (**see Figure**).

GCA should be treated as an ischemic emergency just like cerebrovascular event or myocardial infarction. Implementation of fast-track GCA pathways in rheumatology departments have significantly reduced the risk of permanent sight loss in patients with suspected GCA (15, 16). For GCA, a secondary care ‘fast-track’ referral pathway, combined with GP education, specialists, raising awareness reported a significant reduction in the number of patients experiencing permanent sight loss compared to those going through usual care. Though multifactorial, the reduction in diagnostic delays played a role in achieving this reduction in sight loss. This has also been found to be cost effective. Thus the pathway ‘saves money and saves sight’!

Fast track pathway also helps to minimise the steroid burden in those who do not have GCA or other GCA mimics. Where there is more than a low probability suspicion of GCA, we advocate starting oral glucocorticoids immediately and referral to the fast track clinic since a delay in treatment will have greater consequences than a few days/hours of unnecessary GCs in someone where the diagnosis is thereafter quickly excluded. For GCA patient's preservation of vision and maintenance of Independence are the most important ranked quality of life (QOL) concerns (17). For guidance in adequate triage and referral, a GCA probability score will be helpful and is in development (from the Southend Fast track Clinic) using weighted criteria items such as demographics, mode of onset, symptomatology, ischemic features, inflammatory markers and presence/absence of competing diagnoses such as infection, neoplasia and other head and neck conditions.

1 Amyloidosis

LEARNING OBJECTIVES

- Outline the classification of systemic amyloidosis
- Outline the pathogenesis of amyloidosis
- Outline the epidemiology of systemic amyloidosis
- Describe the clinical manifestations of systemic amyloidosis
- Describe diagnostic approaches to systemic amyloidosis
- Describe treatment options in systemic amyloidosis

1.1 Classification of amyloidosis

Various forms of amyloidosis are characterised by extracellular deposition of fibrillar proteins. Amyloid deposits may be detected by polarisation microscopy, where deposits result in typical green birefringence upon Congo red staining. At least 30 different amyloid proteins have been identified and amyloidosis is classified according to the nature of the major fibrillar protein component (table 1). Amyloidosis can be localised or systemic, inherited or acquired. The interest of the rheumatologist in amyloidosis is twofold: (a) chronic inflammatory rheumatic diseases, such as rheumatoid arthritis (RA), may be associated with (mainly) AA amyloidosis, and (b) some forms of amyloid disease may have musculoskeletal manifestations due to the deposition of amyloid in the joints and periarticular tissues (Falk et al. 1997*; Sipe et al. 2010; Wechalekar et al. 2016*).

As localised amyloidosis only rarely affects the joints, in this module we will discuss features of systemic amyloidoses only, primarily the AA, AL, A β 2M and ATTR forms.

1.2 Pathogenesis of systemic amyloidosis

In amyloidosis, the various proteins misfold and undergo irreversible transition to insoluble and proteolysis-resistant fibrils. In contrast to the heterogeneity of the various precursors, all amyloid fibrils share similar ultrastructure and properties. Amyloid fibrils are rigid, non-branching, 7–13 nm in diameter and of indeterminate length. They are insoluble under normal conditions and their specific highly ordered ultrastructure is responsible for binding Congo red dye in a spatial manner, yielding the characteristic birefringence under polarised light.

Table 1 Classification of systemic amyloidosis (Adapted from Perfetto et al, *Nat Rev Rheumatol* 2010;6:417–29*)

Amyloid type	Fibril protein precursor	Clinical syndrome
AL	Monoclonal immunoglobulin light chains	Associated with plasma cell dyscrasias
AH	Monoclonal immunoglobulin heavy chains	Associated with plasma cell dyscrasias
AA	Serum amyloid A protein	Associated with chronic inflammatory conditions
A β 2M	β 2-Microglobulin	Associated with chronic haemodialysis
ATTR ATTR-SSA	Genetically variant transthyretin Wild-type transthyretin	Familial (autosomal dominant) amyloid polyneuropathy Senile systemic amyloidosis
ACys	Genetically variant cystatin	Hereditary cerebral haemorrhage with cerebral and systemic amyloidosis
AGe	Genetically variant gelsolin	Familial (autosomal dominant) systemic amyloidosis Cranial nerve involvement, lattice corneal dystrophy
ALys	Genetically variant lysozyme	Familial (autosomal dominant) systemic amyloidosis Non-neuropathic, prominent visceral involvement
AApoAI	Genetically variant apoA-I	Familial (autosomal dominant) systemic amyloidosis Non-neuropathic, prominent visceral involvement
AApoAII	Genetically variant apoA-II	Familial (autosomal dominant) systemic amyloidosis Non-neuropathic, prominent renal involvement
AFib	Genetically variant fibrinogen A α chain	Familial (autosomal dominant) systemic amyloidosis Non-neuropathic, prominent renal involvement

High levels of amyloid precursors, including serum amyloid A (SAA) protein, immunoglobulin (Ig) light chain or β 2-microglobulin (β 2M), can be detected in the circulation. For example, the median plasma concentration of SAA in healthy individuals is <5 mg/L, while this may increase to >2000 mg/L during the acute phase response. Amyloid precursors may interact with other non-fibrillar components, such as serum amyloid P (SAP) protein or glycosaminoglycans (GAGs) (figure 1). GAGs promote fibril formation and strengthen their stability.

Amyloid deposition in various tissues may occur under different circumstances.

1. A sustained abundance of otherwise structurally normal proteins, such as SAA or β 2M, may occur during chronic inflammation or renal insufficiency under dialysis, respectively.
2. Some aberrant proteins, such as monoclonal Ig light chains or genetically variant forms of fibrinogen α -chain may form amyloid deposits.
3. Naturally weak amyloidogenic proteins, such as transthyretin (TTR) may be expressed in normal amounts over a prolonged period of time, as seen in senile amyloidosis (Perfetto et al, 2010*, Wechalekar et al. 2016*).

Figure 1 Process of systemic amyloid deposition. Excess production of circulating amyloid precursors occurs under different circumstances leading to misfold protein oligomers. These oligomers bind to serum amyloid P (SAP) and glycosaminoglycans (GAGs) and then are deposited in various internal organs. ApoA, apolipoprotein A; β 2M, β 2-microglobulin; SAA, serum amyloid A; TTR, transthyretin.

Table 3 Conditions associated with systemic AA amyloidosis

Rheumatic diseases	Auto inflammatory syndromes
Rheumatoid arthritis	Familial Mediterranean fever
Ankylosing spondylitis	Hyper-IgD syndrome
Psoriatic arthritis	Muckle–Wells syndrome
Adult-onset Still's disease	TNF receptor-associated periodic syndrome (TRAPS)
Reactive arthritis	Familial cold auto inflammatory syndrome (FCAS)
Juvenile idiopathic arthritis	
Gout	Inflammatory bowel diseases
Systemic lupus erythematosus	Crohn's disease
Sjögren's syndrome	Ulcerative colitis
Systemic sclerosis (scleroderma)	
Systemic vasculitides	Malignancies
Behçet's disease	Lung, colon and urogenital cancer
	Basal cell cancer
Chronic infections	Carcinoid tumour
Tuberculosis	Castleman's disease
Leprosy	Gastrointestinal stromal tumour
Bronchiectasis	Hairy cell leukaemia
Chronic cutaneous ulcers	Hodgkin's disease
Chronic pyelonephritis	Waldenström macroglobulinaemia
Osteomyelitis	Mesothelioma
Q fever	Renal cell carcinoma
Subacute bacterial endocarditis	Sarcoma of the liver
Whipple's disease	Hepatic adenoma
Immunodeficiency states	Other conditions
Common variable immunodeficiency	Cystic fibrosis
Cyclic neutropenia	Epidermolysis bullosa
Hyper-IgM M syndrome	Injected drug abuse
Hypogammaglobulinaemia	Jejunioileal bypass
Sex-linked agammaglobulinaemia	Kartagener's syndrome
HIV/AIDS	Paraplegia
	Sickle cell anaemia
	SAPHO syndrome
	Atrial myxoma
	Sarcoidosis
	Retroperitoneal fibrosis

Ig, immunoglobulin; TNF, tumour necrosis factor.

1.3 Epidemiology, clinical features and prognosis of amyloidosis

Organ and tissue manifestations of amyloidosis are shown in table 2 and figure 1, whereas major clinical syndromes associated with various forms of systemic amyloidosis are included in table 3.

1.3.1 AA amyloidosis

Systemic AA amyloidosis is most commonly associated with chronic inflammatory diseases, including rheumatic, autoimmune and hereditary autoinflammatory disorders, and is also a potential complication of chronic infections and malignancies due to chronic elevations of acute phase reactants, including SAA. In a cohort of 374 patients with AA amyloidosis, 60% of cases were related to chronic inflammatory arthritis, 15% to chronic sepsis, 9% to periodic fever syndromes, 5% to Crohn's disease, 6% to miscellaneous diseases and 6% unknown (Lachmann et al. 2007). A recent large retrospective study identified a pattern of reducing incidence and changing epidemiology with older age of patients at presentation and death, more frequent end stage renal disease (ESRD), as well as a change in aetiology (less juvenile idiopathic arthritis (JIA) patients, more chronic infections due to intravenous drug use) (Lane et al. 2017).

Conditions associated with AA amyloidosis are listed in table 3. SAA is an apolipoprotein of a high-density lipoprotein, which, similarly to C-reactive protein, is synthesised by hepatocytes under the regulation of proinflammatory cytokines, such as tumour necrosis factor α (TNF α), interleukin 1 (IL-1) and IL-6.

RA, ankylosing spondylitis and other arthritides account for approximately 70% of all AA amyloidosis cases. The reported prevalence of amyloidosis in RA varies from study to study depending on the diagnostic procedure used and clinical status. A decreasing incidence of amyloidosis in RA has been demonstrated based on consistent decline of the annual number of biopsies positive for amyloid deposits. The prevalence of the asymptomatic phase of AA amyloidosis in RA ranges between 0.5% and 14%. In ankylosing spondylitis, renal amyloidosis is the most common renal manifestation with a 5-year survival rate of only 30%.

The predominant feature of amyloidosis at diagnosis is renal dysfunction, which manifests as proteinuria or renal failure (figure 2). In 97% of patients >500 mg protein/day was excreted or the serum creatinine concentration was >1.5 mg/dL, or both. Patients with AA amyloidosis may have higher serum creatinine levels at diagnosis and require dialysis earlier than those with AL amyloidosis. If untreated, AA amyloidosis may progress towards ESRD.

Autopsy series or radiolabelled SAP scintigraphy show the presence of amyloid deposits in the liver and spleen, but these deposits rarely lead to clinical manifestations. While hepatic amyloid deposits are found in 25%, hepatomegaly is present in about 10% of all cases of AA amyloidosis. Jaundice or abnormal aminotransferase levels are extremely rare. Splenic involvement is suspected if Howell–Jolly bodies are found in the peripheral blood smear or when frequent infections occur.

Gastrointestinal features include malabsorption, pseudo-obstruction, diarrhoea or vomiting secondary to submucosal amyloid infiltration. Amyloid deposits within vessel walls may lead to gastrointestinal perforation and bleeding.

Cardiac infiltration is present in only 1% of patients with AA amyloidosis, which is much less frequent than in AL amyloidosis. Clinical presentation is right heart failure with lower limb oedema. Cardiomyopathy is an unfavourable prognostic factor.

Few studies have assessed survival rates in AA amyloidosis. The mean survival time in 1991 was 24 months, but it had increased to 79 months by 2008. Higher age, heart involvement and raised serum creatinine levels predict a worse prognosis. Thus, early referral of patients with AA amyloidosis to a nephrologist and co-operation between rheumatologists, internists and nephrologists are needed (Tanaka et al, 2003*; Obici et al, 2005; Perfetto et al, 2010*).

Figure 2 Renal amyloid deposition in a patient with AA amyloidosis secondary to rheumatoid arthritis. (A) Congo red staining. (B) Green birefringence under polarisation microscope. (Courtesy of Dr J Kovács, Department of Pathology, University of Debrecen Medical Centre, Debrecen, Hungary).

1.3.2 AL amyloidosis

AL amyloidosis is the most common type of systemic amyloidosis in Western countries. About 20–30% of patients with myeloma have AL amyloidosis. In this type of amyloidosis, fibrils are derived from monoclonal Ig light chains. AL amyloidosis is usually diagnosed at the age of 60, mostly in men.

The characteristic manifestations of AL amyloidosis are nephrotic syndrome, congestive heart failure, peripheral neuropathy and hepatic involvement (table 2). Multisystem involvement is common (>50%). Renal manifestations including proteinuria and uraemia are seen in about 70% of patients. AL amyloid deposits in the myocardium lead to restrictive cardiomyopathy. Low voltage in the limb leads or poor R-wave progression in the precordial leads is seen on ECG. In 60–70% of patients, echocardiography shows abnormal myocardial relaxation, thickened ventricular walls, pericardial effusion, abnormal myocardial texture and, in late-stage disease, a restrictive filling pattern. Symptomatic involvement of the autonomic and peripheral nervous

systems (20%) includes orthostatic hypotension, axonal and demyelinating peripheral neuropathy or bilateral carpal tunnel syndrome. Hepatomegaly and/or increased transaminase levels are present in almost one-quarter of the patients. Macroglossia is a characteristic feature, which is seen only in AL amyloidosis (table 2).

Rheumatologists may encounter various musculoskeletal manifestations, including joint, bone and soft tissue involvement in 9% of cases. Amyloid infiltration of periarticular and synovial tissues may result in joint swelling and stiffness. The 'shoulder pad' sign is attributable to amyloid infiltration of the tendons and capsules of the shoulders leading to characteristic appearance. Cutaneous ecchymosis around the eyes is also known as 'raccoon eyes'. The shoulder pad sign, raccoon eyes and macroglossia, together found in 10% of patients, are pathognomonic for AL amyloidosis.

Uncommon manifestations include jaw claudication, xerostomia, xerophthalmia, skin manifestations resembling scleroderma, amyloid myopathy mimicking polymyositis, muscle pseudohypertrophy and abnormal bleeding due to acquired factor X deficiency.

Patients with AL amyloidosis have the worst prognosis as heart failure is associated with a median survival time of only 6 months (Falk et al, 1997*; Perfetto et al, 2010*).

1.3.3 β 2-Microglobulin amyloidosis

β 2M amyloidosis is caused by the deposition of fibrillar β 2M and is a serious complication of long-term haemodialysis. The precise mechanism leading to β 2M amyloidosis is still unclear. Amyloid fibril formation has been associated with the duration of renal failure, current age, age at initiation of haemodialysis, duration of haemodialysis and bioincompatibility of dialysis membranes.

The most common manifestations involve the musculoskeletal system (table 2). Early manifestations include carpal tunnel syndrome and arthralgia in the shoulders and other large joints. Arthralgia may later evolve into erosive arthropathy. Spinal involvement is characterised by degeneration of the intervertebral discs and erosions with reactive sclerosis of vertebral plates and little osteophyte formation. Eventually, collapse of vertebral bodies and spondylolisthesis may occur (Perfetto et al, 2010*).

1.3.4 Hereditary amyloidosis

Hereditary amyloidosis is a heterogeneous group of diseases caused by a mutant TTR protein produced by the liver. Mutations may occur in genes encoding apolipoprotein A (apoA)I, apoAII, gelsolin, fibrinogen, lysozyme and cystatin C (table 2). The most important manifestations in ATTR amyloidosis are myocardial dysfunction, peripheral and autonomic neuropathy, secondary skin ulcers and Charcot arthropathy in the lower extremities. Wild-type TTR protein may also form amyloid fibrils leading to senile systemic amyloidosis (Falk et al, 1997*; Perfetto et al, 2010*).

1.4 Diagnostic procedures

Advanced organ involvement has often ensued by the time a clinical diagnosis of amyloidosis is made, so keeping a high index of suspicion is important. Specific combinations of symptoms should trigger suspicion for the diagnosis, such as nephrotic syndrome and heart failure; peripheral and autonomic neuropathy; thick-walled heart failure with normal or low-voltage electrocardiogram; recurrent carpal tunnel syndrome; a combination of carpal tunnel syndrome and heart failure in elderly people; and relevant family history (Wechalekar et al. 2016*). In these patients, biopsy and histological diagnosis is mandatory. Other laboratory tests and imaging should be performed to identify the type of amyloidosis, refine diagnosis and identify clinical manifestations (table 4).

Table 4 Evaluation of patients with suspected amyloidosis*

1.	Characteristic patients	<ul style="list-style-type: none"> • Chronic rheumatic disease • Long-term dialysis • Monoclonal gammopathy
2.	Characteristic clinical manifestations	<ul style="list-style-type: none"> • Non-diabetic nephrotic syndrome • Low voltage on ECG • Echocardiography showing left ventricular hypertrophy • Hepatomegaly, abnormal levels of alkaline phosphatase, γ-glutamyl transferase • Howell–Jolly bodies in peripheral blood smear • Splenomegaly • Chronic demyelinating polyneuropathy and/or orthostatic hypotension • Macroglossia, ‘shoulder pad’ sign, cutaneous ecchymosis • Xerostomia, joint involvement, jaw claudication, skin involvement
3.	Biopsy-histology	<ul style="list-style-type: none"> • Abdominal subcutaneous fat aspiration with Congo red staining • Other biopsies (rectal, renal, liver, salivary gland)
4.	Additional laboratory tests to identify type of amyloidosis	<ul style="list-style-type: none"> • Immunofixation of serum and urine, Ig free light chain assay (AL amyloidosis) • Serum amyloid A assay (AA amyloidosis) • Genetic testing (ATTR amyloidosis) • Serum β2-microglobulin level (Aβ2M amyloidosis)
5.	Imaging	<ul style="list-style-type: none"> • Echocardiography • Abdominal ultrasound (kidney, liver, spleen) • Musculoskeletal ultrasound (joints) • CT, MRI (spinal involvement in β2M amyloidosis) • ^{18}F-FDG PET imaging (pulmonary amyloidosis) • Multimodality imaging (all types) • EMG/nerve conduction study (carpal tunnel syndrome, polyneuropathy)

EMG, electromyogram; Ig, immunoglobulin; FDG PET, fluorodeoxyglucose positron emission tomography.

*See details of the diagnostic algorithm in the text.

1.4.1 Histology

Histological examination of biopsy specimens stained with Congo red under polarised microscopy is the standard method for establishing the diagnosis of amyloidosis. The amyloid deposits are often in a perivascular distribution with some degree of heterogeneity.

Although biopsy specimens can be obtained from compromised organs such as the liver, heart or kidneys, increased blood vessel fragility associated with amyloid deposition carries a risk of bleeding. Therefore, abdominal subcutaneous fat aspiration (ASFA) is preferable. ASFA detects amyloid deposits in patients with AA, AL or ATTR amyloidoses with a sensitivity of 57–88% and a specificity of 100%, whereas it usually gives negative results in A β 2M amyloidosis. The preferred tissue for histology in A β 2M amyloidosis is the synovium. If the ASFA is negative or contraindicated because of local skin infection, haematoma or large umbilical hernia, then biopsy of minor salivary glands may be useful. In AA and AL amyloidosis, salivary gland biopsy has a sensitivity of 86%, and this technique is also useful in ATTR amyloidosis. Rectal biopsy (75–85% sensitivity) was more widely used in the past, but should be deep enough to include the submucosa to be of value. Biopsy of the kidney or liver is sensitive when laboratory tests show dysfunction of the biopsied organ (figure 2). Life-threatening bleeding can occur, and therefore these procedures should be reserved for patients in whom ASFA, salivary gland or rectal biopsy fail to establish the diagnosis. Peripheral nerve biopsies vary in their diagnostic value and may result in residual dysaesthesia.

Some histological techniques may enhance diagnostic performance. ‘Permanganate-sensitive’ deposits stained with Congo red lose their birefringence after oxidation with potassium permanganate. This pattern occurs with AA and A β 2M amyloid. In contrast, AL and ATTR amyloid are ‘permanganate-resistant’. This test was useful in distinguishing between AA and AL amyloidosis, but today it has been replaced by immunohistochemical techniques. In patients with systemic amyloidosis, immunohistochemical studies with antibodies to AA and to the Ig light chains λ and κ are usually sufficient, as they identify the vast majority of amyloid deposits composed of AA fibrils or Ig light chains, but they can be not definitive in AL amyloidosis (Bély and Apáthy, 2000; Sipe et al, 2010). The proteomic method of mass spectrometric analysis of amyloidotic material is the new gold standard for fibril typing (Wechalekar et al. 2016*).

1.4.2 Additional laboratory tests

Knowledge of the type of amyloidosis is a prerequisite to optimal treatment. As AA, AL and ATTR amyloidosis may have similar clinical manifestations (table 2), determination of the type of amyloidosis is particularly important. If characteristic clinical manifestations are present, the biopsy is positive for Congo red staining and green birefringence occurs under polarised light, various laboratory tests may be performed in order to determine the type of amyloidosis (table 4, figure 1).

Immunofixation of serum and urine, as well as an Ig free light chain (FLC) assay should be performed in order to confirm AL amyloidosis. If the diagnosis is uncertain, bone marrow biopsy could be performed (table 4). In patients with chronic inflammatory disease and proteinuria and/or chronic renal failure, increased serum SAA confirms systemic AA amyloidosis (table 4). If AL and AA amyloidoses are excluded, owing to negative immunofixation, an Ig FLC assay and SAA, genetic testing for mutant TTR, apoA-I, apoA-II, gelsolin, lysozyme and cystatin C should be performed in order to confirm ATTR amyloidosis (table 4).

Among laboratory tests, serum troponin, N-terminal portion of type B natriuretic peptide, Ig FLC, β 2M and SAA levels also reflect an unfavourable prognosis (Falk et al, 1997*; Perfetto et al, 2010*).

1.4.3 Imaging

Echocardiography is the 'gold standard' test for diagnosing cardiac involvement. An echocardiogram demonstrating marked left ventricular wall thickening, biatrial enlargement, thickened valve leaflets and a pericardial effusion in the context of reduced ECG voltages is highly persuasive of cardiac amyloid. If either a thickened interatrial septum or a granular highly echogenic myocardium is also present, this makes the diagnosis even more likely (Selvanayagam et al. 2007). Diffuse myocardial granular sparkling has 87% sensitivity and 81% specificity for the diagnosis of cardiac amyloidosis. Senapati et al. (2016) recently studied the use of the regional strain ratio assessed by means of speckle tracking analysis as a means of obtaining better prognostic data than that provided by standard echocardiography. MRI is another highly sensitive technique for the determination of heart involvement. Characteristic MRI features include impaired biventricular systolic function, thickened atrioventricular valves, increased atrial septal thickness and left ventricular mass, and widespread subendocardial hyperenhancement, representing infiltration with amyloid protein.

The SAP component contributes to the stability of amyloid deposits in vivo. This unique property of the SAP component led to the development of a scintigraphic technique capable of detecting amyloid deposits anywhere in the body. Although the definitive diagnosis of amyloidosis continues to depend on histological examination of biopsy specimens, radiolabelled SAP component scintigraphy is both sensitive and specific for detecting amyloid deposits and can be useful in monitoring disease.

Abdominal ultrasound (US) is necessary to investigate renal, splenic and hepatobiliary manifestations of systemic amyloidosis. Musculoskeletal US is a reliable method for detecting amyloid deposits in joints—for example, in the shoulders and wrists of patients with $A\beta$ 2M amyloidosis. Electrophysiology is needed to confirm carpal tunnel syndrome or polyneuropathy as manifestations of the peripheral nervous system primarily associated with ATTR and AL amyloidoses (tables 2 and 4).. As described above, spinal involvement including intervertebral space narrowing, erosions with reactive sclerosis, vertebral plate cysts, vertebral body

collapse and spondylolisthesis may occur in A β 2M amyloidosis. CT may be helpful for assessing the extent of destruction, while MRI may show amyloid deposits in the disc, synovium and ligamentum flavum.

Recently, 18F-fluorodeoxyglucose positron emission tomography (PET) scanning has been introduced to detect pulmonary amyloidosis (table 4). More studies are under way to determine the value of PET in amyloidosis diagnostics.

(Perfetto et al 2010*; Howard et al, 2012; Baqir et al, 2014).

1.5 Current and new treatments

1.5.1 General therapeutic strategies

No treatment specifically stimulates the clearance of amyloid deposits and, therefore, strategies focus on reducing the supply of the respective amyloid fibril precursor protein while supporting or replacing the function of the affected organs. Although these treatments may have significant toxicity and the clinical benefit is often delayed by months or years after the supply of the fibril precursor has been reduced, this strategy often slows disease progression, permits gradual regression of amyloid deposits and eventually, leads to improved survival.

In systemic amyloidosis secondary to inflammatory rheumatic diseases, the strategy involves administration of anti-inflammatory drugs, including non-steroidal anti-inflammatory drugs and glucocorticoids, as well as various traditional or biologic immunosuppressive agents. Among the biological agents, TNF α inhibitors suppressed proteinuria and gastrointestinal amyloid deposition in AA amyloidosis secondary to arthritis. Targeting IL-1 with anakinra and, more recently, canakinumab seems particularly interesting in autoinflammatory syndromes complicated by amyloidosis. As IL-6 is also involved in the pathogenesis of amyloidosis, as well as arthritis, IL-6 receptor inhibition by tocilizumab may also be promising.

There have been approaches to inhibiting fibrillogenesis in amyloidosis. As described above, proteoglycan GAG chains are universal constituents of amyloid deposits (figure 1). New sugar analogues of N-acetylglucosamine inhibit the binding between heparan sulfate or the heparan sulfate proteoglycan perlecan and amyloid fibril proteins, and orally administered low molecular weight anionic sulfonate or sulfated compounds can substantially inhibit the development of experimentally induced murine AA amyloid. A GAG mimetic agent eprodisate has been developed and introduced to human trials, but results are still awaited (Dember et al. 2007).

Although direct induction of amyloid deposit regression has not yet been a feasible approach, there have been attempts to target the SAP component described above. The non-fibrillar SAP is universally present in amyloid deposits, persists within these deposits for prolonged periods and can be identified by SAP scintigraphy. Small

molecular compounds that inhibit the binding of SAP to amyloid fibrils are under investigation (Fiter et al, 1995; Kyle et al, 1997; Stankovic and Grateau, 2011).

1.5.2 Treatment of AA amyloidosis

In AA amyloidosis secondary to inflammatory rheumatic diseases, the major goal of treatment is to control the underlying disease. Chronic suppression of SAA production leads to the regression of amyloid load and deposition as determined by SAP scintigraphy. This will eventually lead to clinical improvement and improved long-term survival.

Various immunosuppressive agents, including colchicine, methotrexate (MTX), cyclophosphamide, chlorambucil and leflunomide, have been used in an attempt to control secondary AA amyloidosis associated with arthritis. These agents reduced SAA levels. Apart from scattered early case reports showing limited efficacy, no large trials have been conducted. Colchicine treatment was only effective in secondary renal amyloidosis with low proteinuric stage, but not in amyloidosis associated with rheumatic diseases. Colchicine is mainly used to treat AA amyloidosis secondary to familial Mediterranean fever (FMF).

Biological agents have emerged as effective drugs for the treatment of secondary renal and gastrointestinal AA amyloidosis. Among TNF α inhibitors, etanercept and infliximab reduced proteinuria and inhibited gastrointestinal amyloid deposit formation in patients with arthritis. The IL-1 inhibitor anakinra has been successfully used in cases of amyloidosis secondary to auto inflammatory syndromes, including TNF receptor-associated periodic syndrome (TRAPS), cryopyrin-associated periodic syndrome (CAPS), FMF, Muckle–Wells syndrome and familial cold auto inflammatory syndrome. The T cell costimulation inhibitor abatacept was also effective in some cases of AA amyloidosis secondary to arthritis. Because of its potent anti-IL6 action, tocilizumab may be efficacious in treating AA amyloidosis regardless of the underlying cause. It has successfully controlled AA amyloidosis complicating RA, JIA and adult-onset Still's disease (AOSD). Tocilizumab improved nephrosis, as well as gastrointestinal amyloid deposition and diarrhoea.

In a phase II/III clinical trial, the effects of eprodisate, a small molecule GAG mimetic, were compared with those of placebo in patients with systemic AA amyloidosis. Although the specified primary end point for efficacy was not achieved, eprodisate significantly slowed the progression of renal disease in comparison with placebo. Thus, inhibition of interactions between GAGs and amyloid fibrils using small molecule anionic sulfates or sulfonates remains a promising therapeutic approach in all types of amyloidosis

(Fiter et al. 1995; Gottenberg et al 2003; Keersmaekers et al, 2009; Unverdi et al. 2013; Nakamura et al. 2014; Courties et al. 2015).

1.5.3 Treatment of AL amyloidosis

In AL amyloidosis, chemotherapy reduces the production of amyloid precursor proteins, which improves target organ function and survival. Future therapeutic strategies will aim to inhibit fibrillogenesis by stabilising precursor proteins or to promote amyloid clearance. Determination of serum Ig FLC levels has important prognostic value and also reflects the response to chemotherapy.

Among therapeutic strategies, high-dose melphalan followed by autologous stem cell transplantation was effective in haematological patients with AL amyloidosis. Complete haematological response leading to prolonged survival could be achieved in 40% of patients. As cardiac involvement was associated with higher treatment-related mortality, such patients should receive other chemotherapy regimens. The main causes of cardiac worsening are heart failure and ventricular arrhythmias (VAs), but there is still debate concerning the need and indication for implantable cardioverter-defibrillator (ICD) therapy (Hamon et al. 2016). Other pharmacological strategies include the combination of melphalan with glucocorticoids; however, this treatment resulted in a 28% response rate. In relapsing cases, thalidomide may be an effective alternative, but it has been poorly tolerated by patients with polyneuropathy. A new and less toxic thalidomide analogue, lenalidomide induced haematological responses in 67% of patients. The proteasome inhibitor bortezomib, registered for the treatment of multiple myeloma, produced responses in 50% of patients when administered in monotherapy and in >80% of patients in combination with dexamethasone (Fitter et al, 1995; Perfetto et al, 2010*; Kastritis and Dimopoulos 2016).

1.5.4 Treatment of A β 2M amyloidosis

In A β 2M amyloidosis, the approach is to prevent amyloid deposition by removing β 2M using high-flux dialysis membranes and adsorption columns. There is insufficient evidence that these manipulations will indeed decrease amyloid deposits (Perfetto et al, 2010*).

1.5.5 Treatment of ATTR amyloidosis

Liver transplantation seems to be the only way to remove the source of mutated TTR from the blood. Blockade of TTR fibrillogenesis may be a feasible approach in the future. Small molecules that stabilise the tetramer structure of TTR would inhibit its dissociation and would prevent the formation of cytotoxic monomeric species. Such agents include tafamidis, diflunisal and a combination of doxycycline and tauro-ursodeoxycholic acid (TUDCA). Finally, novel RNA inhibiting therapies targeting the synthesis of transthyretin in the liver are under development (Wechalekar et al. 2016*).

1.5.6 Treatment follow-up

As described above, some laboratory biomarkers may reflect the progression and prognosis of various types of amyloidosis. Thus, these markers may be used to monitor therapeutic response. Circulating SAA, β 2M levels and the Ig FLC assay may be repeatedly used to monitor therapeutic response in AA, A β 2M and AL amyloidosis, respectively (table 4).

In AA amyloidosis secondary to chronic rheumatic diseases, organ involvement may develop after a period of time. Therefore, these patients must be periodically monitored for new clinical symptoms and laboratory tests, such as renal function and microalbuminuria, must be carried out. These patients are at high risk of rapid acceleration of amyloidosis, and new organ manifestations may occur at any time (Tanaka et al, 2003*; Perfetto et al, 2010*).

SUMMARY POINTS

- Systemic amyloidosis is characterised by extracellular deposition of insoluble fibrils.
- Amyloidosis is classified by the nature of amyloid precursor proteins.
- The type of amyloidosis greatly influences the required treatment and outcome.
- The diagnosis of amyloidosis needs histological confirmation.
- Extensive investigation should be performed to determine systemic organ manifestations.
- Treatments aim to reduce the supply of amyloid precursor proteins.
- Future therapeutic strategies aim to inhibit fibrillogenesis by stabilising precursor proteins or to promote amyloid clearance.

2 Atherosclerotic disease in patients with inflammatory arthritis and systemic lupus erythematosus

LEARNING OBJECTIVES

- To describe the epidemiology of cardiovascular disease in rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, and systemic lupus erythematosus (SLE)
- To describe the contribution of traditional cardiovascular risk factors to the excess cardiovascular risk
- To describe the contribution of disease-specific processes to the excess cardiovascular risk
- To describe the effects of treatments on endothelial function
- To describe the effects of treatments on cardiovascular risk factors and cardiovascular morbidity
- To describe measures for preventing cardiovascular disease in patients with inflammatory arthritis and SLE

2.1 Cardiovascular mortality

2.1.1 Rheumatoid arthritis

Mortality in rheumatoid arthritis (RA) is increased compared with the general population. Standardised mortality ratios (SMRs) in observational studies ranged from 1.3 to 3.0 but recent meta-analyses show somewhat lower SMRs (1.2-1.7) (Avina-Zubieta et al. 2008; Widdifield et al. 2015; Dregan et al. 2017; Gwinnutt et al. 2017). Excess mortality is largely due to cardiovascular diseases (CVDs), particularly atherosclerotic ischaemic heart disease. The Norfolk Arthritis Register has confirmed an increase in all-cause and CV mortality in patients satisfying the 2010 American College of Rheumatology/European League Against Rheumatism (ACR/EULAR) criteria for RA; there were 40% more deaths than expected in rheumatoid factor (RF)/anti-citrullinated peptide antibody (ACPA)-positive than in RF/ACPA-negative patients, suggesting that antibody status plays an important role in CV mortality (Humphreys et al. 2014). There has been debate on the trend of cardiovascular (CV) mortality in RA. A systematic review and meta-analysis suggests a decrease in incident mortality of 2.3% a year (95% CI 2.1% to 2.6%) and a meta-SMR of 1.47 (95% CI 1.19 to 1.83), with no decrease over time in the meta-regression (Dadoun et al. 2013). More recent data support also a reduction in CV-related mortality (Myasoedova et al. 2017)

2.1.2 Spondyloarthropathies

Mortality has been less investigated in the spondyloarthropathies but is also high, although less so than in RA. Reported SMRs for ankylosing spondylitis (AS) are between 1.5 and 1.9 (Bakland et al. 2011; Haroon et al.

2015; Exarchou et al. 2016) and even lower in psoriatic arthritis (PsA), between 0.8 and 1.6. In a recent study from Swedish registries, SMRs for overall and cardiovascular mortality were 1.22 and 1.64 respectively and they were associated with disease activity (Juneblad et al. 2016).

2.1.3 Systemic lupus erythematosus

Mortality in patients with systemic lupus erythematosus (SLE) typically has a bimodal pattern: this is driven by infectious complications in the early phases, but CVD is by far the most important contributor to the second (late) peak of mortality. Although mortality has improved greatly in SLE over the past few decades, it is still 2–5 times higher than in the general population with CV morbidity being also significantly higher (Symmons and Gabriel 2011).

2.2 Cardiovascular morbidity

2.2.1 Rheumatoid arthritis

A number of studies have indicated that patients with RA are at higher risk of developing CV diseases such as myocardial infarction (MI), cerebrovascular disease, peripheral arterial disease (PAD) and congestive heart failure (CHF). In a meta-analysis, RA patients had a 48% increase in the risk of incident CVD compared with the general population, 68% for MI, 41% for a CV event and 87% for CHF (but only in women)(Avina-Zubieta et al. 2012*). In a recent comparison between sex and age-matched patients with RA or osteoarthritis (OA) in a Chinese population, the adjusted ORs (95%CI) for CVD, stroke, IHD, CHF, and atherosclerosis were 1.86(1.42-2.43), 1.11(0.71-1.74), 1.47(0.97-2.24), 2.09(1.03-4.22), and 2.49 (1.97-3.13), respectively (Zou et al. 2017).

The prospective Dutch CARRÉ (CARDiovascular research and Rheumatoid arthritis) study of 353 patients with RA diagnosed between 1989 and 2001, investigated the magnitude of this risk by comparing prevalent CVD and diabetes (a well-established CV risk factor) with the findings of the Hoorn population-based cohort study of CVD and its risk factors (van Halm et al. 2009): its findings suggested that the risk of CVD in RA patients is increased to an extent comparable to that seen in diabetes. This has recently been confirmed in the much larger nationwide Danish study: the overall, fully adjusted incidence rate ratio of MI in patients with RA was 1.7 (95% CI 1.5 to 1.9), the same as that found in patients with diabetes 1.7 (95% CI 1.6 to 1.8) (Lindhardsen et al. 2011). Various other studies have found that patients with RA have a 2–4 times greater risk of developing MI than the general population, and that the occurrence of multivessel coronary disease is twice as frequent in patients with RA who have had an MI than in patients with an MI but without RA, thus indicating accelerated atherosclerosis. In addition, the fatality rate after MI is almost twice as high in patients with RA in both the short term (30 days) and the long term (up to 10 years). Although ischemic heart disease (IHD) in RA probably follows a decreasing trend (Holmqvist et al. 2017), it is still high comparing to the general population. It is

important to note that patients with RA are less likely to report angina, and twice as likely to experience a silent MI and sudden death.

CHF is also an important co-morbidity in RA. A population-based, retrospective incidence cohort study of 575 patients with RA and 583 controls using the criteria of the Framingham Heart Study found that the incidence of CHF was, respectively, 2.0 and 1.2 per 100 person-years (rate ratio 1.7, 95% CI 1.3 to 3.2.), the cumulative incidence after a follow-up of 30 years was, respectively, 34% and 25% (HR = 1.9) and the risk was higher in RF positive patients (Nicola et al. 2005). Recent results from two Swedish cohorts also show increased risk for both ischemic and non-ischemic CHF (HRs 1.71 and 1.88 respectively). There appears to be a rapid increase of risk for non-ischemic CHF in newly diagnosed RA patients, not fully explained by their IHD risk but associated with high disease activity (Mantel et al. 2017). A major drawback of heart failure studies in RA is that the diagnosis is usually based on clinical criteria, thus making it less reliable than a diagnosis based on echocardiographic criteria. Diastolic heart failure with preserved ejection fraction seems to be more prevalent reflecting the influence of chronic inflammation on the myocardium (Nurmohamed et al. 2015*; Midtbø et al. 2016b), while high ACPA titres were associated with increased left ventricular (LV) mass index (Geraldino-Pardilla et al. 2017).

It is important to remember that the prevalence of CVD may vary from country to country, as was recently demonstrated by a large cross-sectional study of 4363 patients from 15 countries. The overall prevalence of CVD (defined as MI, angina, coronary heart disease, coronary bypass surgery or stroke) was 9%, but ranged from 3.6% to 17.8%: <5% in France and Argentina, and >10% in Finland, Germany, Poland, the UK and the USA (del Rincón et al. 2007; van Halm et al, 2009; Peters et al, 2010).

2.2.2 Spondyloarthropathies

Available data on CV morbidity in AS and PsA indicate increased CV risk, perhaps comparable to that of RA (Peters et al. 2004).

Han et al. (2006)* used the large American PharMetrics medical reimbursement administrative database of 1843 patients with AS to find prevalence odds ratios of 1.3 for ischaemic heart diseases, 1.4 for CHF, 1.6 for atherosclerosis and 1.3 for cerebrovascular disease in comparison with the controls. Increased CV risk in AS is related to higher inflammatory activity (Bakland et al. 2011). A systematic review and meta-analysis of observational studies that compared the risk of coronary artery disease in patients with AS versus non-AS controls showed that AS was associated with a 1.41-fold [95% CI: 1.29-1.54] increased risk of coronary artery disease compared with non-AS patients (Ungprasert et al., 2015). A Swedish population study also found a more than twofold higher prevalence of IHD (Bremander et al. 2011). In contrast, a population-based cohort study using the British Clinical Practice Research Datalink found only a non-significant trend for IHD in women with AS, after adjusting for NSAID use (Essers et al. 2014).

A number of studies indicate that AS is also associated with various non-atherosclerotic CV manifestations. The inflammatory processes in AS may affect different structures of the heart: the most characteristic lesions are conduction defects and aortic insufficiency, but other less common manifestations are pericarditis, cardiomyopathy and mitral valve disease. Conduction disturbances may occur in AS because of inflammation and fibrosis of the membranous portion of the interventricular septum, thus affecting the atrioventricular node. The reported prevalence rates vary from 1% to 33%, and may be related to the presence of HLA-B27. One recent study found no increase in comparison with historical controls, whereas a study of 131 consecutive patients with AS found intraventricular conduction disturbances in up to 30% (Atzeni et al. 2010; Szabo et al. 2011). These data have been confirmed by a recent meta-analysis showing that, compared to controls, patients with AS have an increased prevalence of diastolic left ventricular dysfunction, which may be a precursor of CHF (Heslinga et al. 2014). Aortic insufficiency develops because the aortic inflammatory process affects the aortic wall directly behind and above the sinuses of Valsava. The reported prevalence rates range from 1% to 10%, and increase with age, disease duration and presence of peripheral arthritis.

The number of publications concerning CV morbidity in patients with psoriasis and PsA has increased in recent years. A database investigation of 648 patients with PsA found a 2.5 increased standardised prevalence of MI, and the same group also showed that the CV risk was higher than in patients with psoriasis alone. A questionnaire-based survey of 753 patients with PsA showed that the prevalence rates of ischaemic CVDs were comparable with those found in patients with RA (Atzeni et al. 2011). A meta-analysis showed an increased risk of MI in patients with psoriasis (OR = 1.25, 95% CI 1.03 to 1.52) or PsA (OR = 1.57, 95% CI 1.08 to 2.27) in comparison with the general population, but inconclusive results for stroke (Horreau et al. 2013).

Disease activity was independently associated with CV morbidity in a Canadian large PsA cohort study (Eder et al. 2016). A recent meta-analysis of observational studies confirmed increased morbidity risks for MI, cerebrovascular disease and heart failure (pooled OR 1.68 [95% CI 1.31-2.15], 1.22 [1.05-1.41] and 1.31 [1.11-1.55], respectively) in patients with PsA (Polachek et al. 2017).

Patients with psoriasis have increased incidence of both heart failure (HR :1.22-1.53) and arrhythmia (HR: 1.25-1.46) depending on disease severity and presence of arthritis (Khalid et al. 2014; Chiu et al. 2015).

2.2.3 Systemic lupus erythematosus

Prospective cohort studies of patients with SLE have shown high rates of CV morbidity, with a prevalence of CV events of 6–10% and an annual incidence of 1.5%. In fact, SLE is associated with the highest CV morbidity risk amongst rheumatic diseases (Koenig et al. 2015).

CV risk was 5–6 times higher in the Pittsburg cohort of patients with SLE than in the Framingham cohort and, in women aged 35–44 years, it was 50 times higher than in controls. A Swedish study of SLE patients followed

up for 6 years found that MI occurred nine times as often as in the general population, while the prospective Nurse's Health study found that the risk was lower (a 2.2-fold increased risk). The higher incidence of MI is associated with a longer disease duration and glucocorticoid treatment. Epidemiological studies cannot determine whether the increased risk of CVD is due to accelerated atherosclerosis or to a greater susceptibility to thrombotic complications but histopathological studies suggest the presence of subclinical atherosclerosis (Bruce et al. 2003; Roman et al. 2003; Mosca et al. 2010*; Skaggs et al. 2012*; Matsuura et al. 2014). A recent Danish nationwide cohort study identified high risk for MI (HR: 2.2), stroke (HR: 2.1) and CV mortality (HR: 1.6) in patients with SLE. The risk for MI, CV mortality but not for stroke is particularly increased in SLE patients with lupus nephritis (Hermansen et al. 2017).

2.3 Preclinical atherosclerosis

Carotid artery intima media thickness (IMT) is a suitable means of assessing early preclinical atherosclerosis and a predictor of future CV disease. A landmark general-population study found that every 0.20 mm increase in cIMT is associated with a 30% increase in new CV events and, when IMT is divided into quintiles from <0.87 mm to >1.18 mm, the relative risk for new CVD is tripled between the fifth and first quintile. Consequently, given the increased CV risk in patients with RA, a number of investigators have measured cIMT in more than 20 studies and, taken together, have found that it is almost 0.1 mm thicker in patients than matched controls. This increase seems to be related to disease activity parameters but is much less than expected in the light of the doubled CV risk: this suggests that the problem may also be due to plaque instability.

The presence of carotid plaques has been linked to IHD and poor CV-related survival in RA patients (Evans et al. 2011). Del Rincón et al. (2007) observed that the rate of IMT progression was related to disease duration, and ranged from 0.15 mm/10 years in patients who have had the disease for <7 years to 0.30 mm/10 years in patients who have been affected for >20 years. Patients with longstanding RA, therefore, have more atherosclerosis than patients of the same age but with shorter disease duration, thus indicating that RA accelerates atherosclerosis. The clinical relevance of preclinical atherosclerosis was also assessed in a cohort of RA patients. A coronary event occurred in six of the 10 patients with a baseline IMT of >0.91 mm, but in none of those with a baseline IMT of <0.77 mm (Gonzalez-Juanatey et al. 2009*). A prospective study also identified increased subclinical atherosclerosis in RA patients by measuring both IMT and flow-mediated dilatation (FMD) after a 5-year follow up. The extent of this effect could be predicted by the presence of traditional CVD factors, as well as inflammatory load over time (Södergren et al. 2015). However, further large-scale studies are necessary to confirm these findings.

The number of publications concerning preclinical atherosclerosis in patients with AS or PsA is limited. Arida et al. (2015) showed that carotid IMT, but not plaque burden, was significantly increased in AS compared to controls but only in active disease patients (based on BASDAI \geq 4). FMD of the brachial artery has also been

found significantly impaired in AS patients. This is an important finding as it is thought that endothelial dysfunction is the initiating step in atherosclerosis (Bodnár et al. 2011). Various controlled studies of patients with PsA have shown increased IMT and significantly impaired FMD. However, none of these studies showed a clear correlation with disease activity, possibly because of a type II error.

Patients with SLE and CV manifestations (eg, MI, angina, stroke and/or arterial claudication) have increased IMT in comparison with patients with SLE without CV manifestations and controls. Subclinical atherosclerosis (as identified by carotid plaques) has also been proven to occur early in SLE patients and is probably driven by disease-related factors (Roman et al. 2003). A recent study indicated that the relative risk of carotid and femoral atherosclerotic plaques in SLE was comparable to that of RA and diabetes (RR=1.80, 95% CI 1.05-3.08) (Tektonidou et al. 2017).

Non-invasive imaging techniques that measure atherosclerosis (IMT), endothelial dysfunction (FMD) and arterial stiffness (pulse-wave velocity) are useful for detecting preclinical vascular disease in arthritides and autoimmune diseases (Soltész et al. 2011; Kerekes et al. 2012). The use of carotid US helps reclassify a considerable proportion of patients to a more appropriate CVD risk group in RA (Corrales et al. 2014), AS (Rueda-Gotor et al. 2016) and PsA (Martínez-Vidal and Fernández-Carballido 2017). The updated EULAR recommendations for CVD risk management suggest to consider screening for asymptomatic atherosclerotic plaques with carotid US as part of the CVD risk evaluation for RA patients (Agca et al. 2017*).

2.4 Cardiovascular risk factors

2.4.1 Rheumatoid arthritis

2.4.1.1 Dyslipidaemia

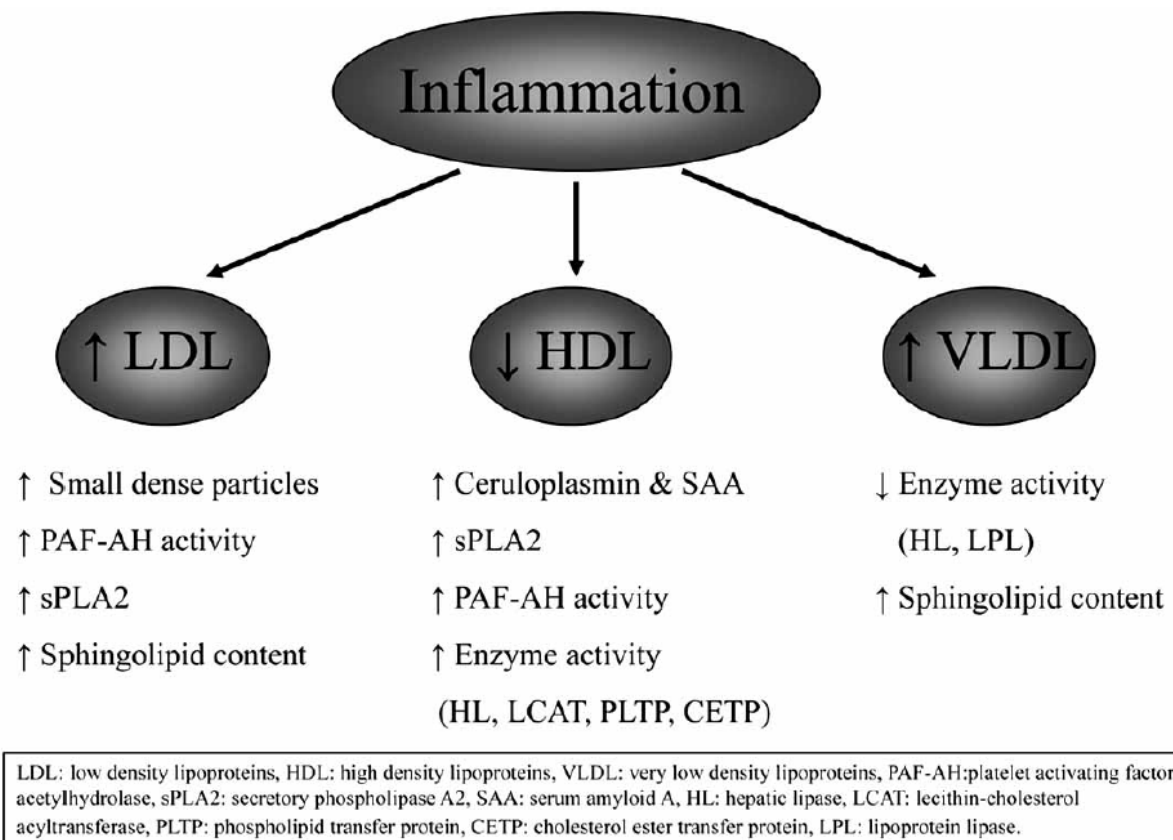

In the general population, high levels of total cholesterol (TC) and LDL cholesterol (LDL-C) and low levels of high-density lipoprotein (HDL) cholesterol (HDL-C) are associated with an increased risk of CVD. In RA however, this relationship paradoxical ('lipid paradox') due to an inverse relationship between lipid levels and disease activity: greater disease activity is related to lower TC and LDL-C levels (figure 3) (Myasoedova et al. 2011*; Myasoedova 2017*). The presence of even more depressed HDL-C levels leads to a higher (unfavourable) atherogenic index (TC/HDL-C ratio). The explanation of this 'paradox' may lie on genetic factors, decreased LDL synthesis and/or increased lipid clearance in patients with active RA, with a recent study demonstrating the latter (Charles-Schoeman et al. 2015). Furthermore, protecting LDL from oxidation is one of the anti-atherogenic roles of normal HDL-C, which can be distinguished from the so-called proinflammatory HDL-C that does not have this property and may actually promote inflammation. Proinflammatory HDL-C was detected in 20% of 48 patients with RA and in only 4% of 72 controls (Kerekes et al. 2014*).

It seems that dyslipidaemia is already present in early RA, which raises the question as to whether it starts in the preclinical phase. Lipid profiles and their relationships with inflammation and serological markers in subjects who later developed RA were investigated. The samples of the patients with future RA had higher TC, triglyceride and apoB levels and lower HDL-C compared to matched controls at least 10 years before the onset of symptoms. Although the differences were small, they may be clinically relevant (Choy and Sattar 2009; Robertson et al. 2013).

Measurement of plasma apolipoprotein A-I (apoA-I), present in HDL-C particles, and apolipoprotein B (apoB), which is found in LDL-C, very low-density lipoprotein (VLDL) and chylomicron particles, may help to assess the total number of pro- and anti-atherogenic particles. There is accumulating evidence that apoB is a better predictor of CV events than LDL-C, and that the apoB/apoA-I ratio is an accurate predictor of CVD insofar as apoA-I might be protective and apoB might increase susceptibility to new CV disease. RA disease activity inversely correlated with apoA-I and HDL-C levels, thus suggesting genetic coupling between dyslipidaemia and the development of RA. Furthermore, it has recently been shown that four RA susceptibility genes (PTPN22, TRAF1/C5, STAT4 and the shared epitope) are associated with TC, LDL-C, apoA-I and apoB levels (Toms et al. 2011a*, 2011b*; Kerekes et al. 2014*).

A growing body of literature shows that reducing inflammation by disease-modifying antirheumatic drugs (DMARDs), including early glucocorticoids, has beneficial effects on the lipid profiles of RA patients, leading to an increase in TC and LDL-C and a more pronounced increase in HDL-C and, consequently, a lower (more favourable) atherogenic index (Chen et al. 2015*; Provan et al. 2015; Souto et al. 2015; Charles-Schoeman et al. 2016a*).

Figure 3 The effects of inflammation on the structure, composition and function of lipids (Reprinted with permission from Toms TE et al, *Curr Vasc Pharmacol*. 2010 May;8(3):301–26)

2.4.1.2 Smoking

Smoking is a well-known risk factor for both CVD and RA. RA patients are more frequently current or ex-smokers than the general population (Boyer et al. 2011). There is a causal link between smoking and RA and smoking has been associated with more severe clinical RA presentation and decreased response to DMARD treatment. However, possibly because of the many overlying interactions with other factors, it has been difficult to clearly establish quantitatively the contribution of smoking to CVD risk in RA populations (Nurmohamed et al. 2015*). In a recent meta-analysis, CV morbidity in RA increased with smoking (RR=1.50) (Baghdadi et al. 2015*).

2.4.1.3 Hypertension

The prevalence of arterial hypertension in RA patients ranges from 4% to 73%, although the recent international COMORA study calculated it at 40.4% (Dougados et al. 2014*). However, data on whether it is more frequent than the general population has been conflicting (Boyer et al. 2011; Protogerou et al. 2013). Undoubtedly, it is an important CVD risk factor and was recently associated with asymptomatic CV organ damage in RA (Panoulas et al. 2010; Midtbø et al. 2016a). The mechanisms behind its pathophysiology in RA are various and include the poor adaptive ability of the arterial system in blood flow changes, increased

arterial stiffness and peripheral vascular resistance, the presence of specific genetic polymorphisms, the activation of inflammatory pathways and the effect of RA treatment (Panoulas et al. 2007, 2008c*).

Unfortunately, hypertension is both underdiagnosed and undertreated in RA (Van Breukelen-van der Stoep et al. 2016) and more aggressive management appears mandatory.

2.4.1.4 Body mass index (BMI), obesity and physical inactivity

As with lipid changes, the effect of BMI in CVD risk in RA populations seems also paradoxical. In the general population, normal-to-low BMI is protective in terms of CVD risk. In contrast, low BMI in RA has been associated with higher risk for CV morbidity. This is explained by the effect of systemic inflammation on adipose tissue leading to muscle atrophy and fat accumulation (low muscle mass, high fat percentage) which has been termed rheumatoid cachexia (figure 4) (Kremers et al. 2004; Summers et al. 2010). These pathophysiological changes are underappreciated with the use of the general population's BMI thresholds and alternative tools, such as the waist-to-hip ratio, may be more representative. This increased visceral adiposity and sarcopenic obesity is positively associated with hypertension, increased insulin resistance, metabolic syndrome and inflammatory load (Stavropoulos-Kalinoglou et al. 2009, 2011*). Furthermore, the physical inactivity that characterises RA patients for a number of reasons (joint pain and stiffness, fear of disease exacerbation, psychological barriers) has also been associated with increased CVD risk (Metsios et al. 2009; Hernández-Hernández et al. 2014). Several studies have also proven that high intensity structured exercise is beneficial in reducing long-term inflammation and in improving both micro- and macro-vascular function in RA (Khoja et al. 2016). Thus, physical activity should be encouraged in this population and is a part of the lifestyle interventions recently recommended by EULAR (Agca et al. 2017*).

2.4.1.5 Diabetes, insulin resistance and metabolic syndrome

As with obesity, insulin resistance and metabolic syndrome appear to be associated with RA, a process mainly driven from systemic inflammation (Dessein et al. 2003; Chung et al. 2008; Giles et al. 2015). This is a bidirectional relationship, as insulin resistance causes low-grade inflammation, but also high RA disease activity precipitates the effects of metabolic syndrome (Zegkos et al. 2016*). Moreover, both synthetic and

Figure 4 Summary of current knowledge regarding the underlying mechanisms and clinical manifestations of rheumatoid cachexia. The question marks denote areas in which the current state of knowledge is still preliminary. (Reprinted with permission from Summers GD et al, *Nat Rev Rheumatol.* 2010 Aug;6(8):445–51)

biological DMARD treatment in RA reduces the risk for development of diabetes and improves insulin resistance, as has been shown in several studies (Toms et al. 2009; Burska et al. 2015; Chen et al. 2015*; Bissell et al. 2016).

2.4.1.6 RA-specific risk factors

The chronic high-grade inflammatory state of RA and disease severity, as proven by joint involvement and extra-articular manifestations are established CVD risk factors in this population. Several inflammatory and serological RA markers (ESR, CRP, RF, ACPA) have been positively associated with CVD risk, while reduced time-averaged disease activity in RA is associated with less CV events (Solomon et al. 2015). RA and atherosclerosis share common inflammatory pathways (Skeoch and Bruce 2015), while immune activation/dysregulation, such as that seen in RA, is considered an important CVD risk factor. RF and ANA impose increased risk for IHD, CHF and peripheral vascular disease, independent of a diagnosis of RA (Liang et al. 2009), while ACPA positivity has been shown to promote atherosclerosis (Spinelli et al. 2017).

As disease severity is associated with increased mortality, it is reasonable to assume that the genes associated with disease severity are also associated with mortality. The HLA-DRB1 alleles encoding shared epitopes (SEs) are the most important and their effect to CVD mortality increases in combination with other risk factors. The HLA-DRB1*0101/*0401 and 0404/*0404 genotypes are very strong predictors of mortality with HRs of, respectively, 5.1 and 7.6, probably by relating to T cell-mediated vascular inflammation and damage. More recently discovered susceptibility risk alleles for RA located at the CCL21 locus are also associated with increased CV mortality. A number of studies have found that the gene polymorphisms associated with a higher CV risk in patients with RA, such as the TNF -308 (rs1800629), rs599839 A/G polymorphism, MIA3 rs17465637 A/C and it has been suggested that the risk may also be influenced by the CCR5Δ32 deletion, MTHFR 1298 A > C and IL6-174 gene polymorphisms (Rodríguez-Rodríguez et al. 2012). Associations of several genetic polymorphisms with hypertension and dyslipidaemia have also been described in patients with RA (Panoulas et al. 2008a, 2009a, 2009b; Toms et al. 2011b*, 2012). However, all of these associations need to be confirmed in much larger studies.

2.4.2 Spondyloarthropathies

The published data concerning the lipid profiles of patients with AS or PsA are somewhat contradictory, possibly because of differences in disease activity in the populations studied (Atzeni et al. 2011; Bodnár et al. 2011). As in RA, it seems that the degree of inflammation plays a role in the magnitude of dyslipidaemia. Lipid levels and inflammation markers (C-reactive protein and serum amyloid A (SAA)) were investigated during anti-TNF treatment in 92 patients with AS, in a subgroup of whom HDL-C composition was also analysed. All the inflammatory markers decreased during anti-TNF treatment; TC, HDL-C and apoA-I levels significantly increased; while SAA concentrations in HDL particles were high at the start of treatment, but subsequently decreased. This may be important because SAA replaces apoA-I in HDL particles and thus impairs the anti-atherogenic properties of HDL-C: consequently, by decreasing SAA concentrations the atheroprotective effects of HDL-C are restored.

A few small studies have shown that hypertension occurs more often in patients with AS or PsA than in the general population. The large database of Han et al has confirmed these observations by showing that hypertension is 30% more common in such patients (Han et al. 2006*). Data from the large NOCAR project showed that hypertension and obesity were more frequent in PsA compared to RA and AS. In the same study, hypertension was associated with disease activity in RA and AS (Wibetoe et al. 2017*). Insulin resistance and the metabolic syndrome have been traditionally associated with psoriasis but data in AS are too limited to allow any definite conclusions.

2.4.3 Systemic lupus erythematosus

The increased prevalence of CV disease is well established in SLE even after correction for traditional risk factors. Several associations with disease related clinical, genetic and immunological features have been described (Giannelou and Mavragani 2017*).

A Canadian case–control study of 250 consecutive patients with SLE and 250 controls found higher rates of hypertension and diabetes mellitus in patients who were less physically active and had higher levels of VLDL-cholesterol, triglycerides and homocysteine. The CV risk estimate based on the Framingham score was not significantly different between the groups.

High cholesterol levels and a diagnosis late in life are two factors that are consistently associated with an increased CV risk in patients with SLE. A prospective study of 134 patients showed that cholesterol levels consistently >5.2 mmol/L independently predict MI or unexplained sudden death, which occurred in 28% of the patients with consistently high cholesterol levels and in only 3% of those with consistently normal cholesterol levels. Nevertheless, conventional risk factors do not fully explain the increased CV risk associated with SLE: in a cohort of 296 patients with SLE followed up for mean period of 8.6 years, the RR (95%CI) adjusted for conventional risk factors were: 10.1 (5.8 – 15.6) for MI, 17.0 (8.1-29.1) for CV death and 7.9 (4.0-13.6) for stroke (Esdaile et al. 2001).

A case–control study comparing 8688 patients with acute MI and 33 923 controls in the UK General Practice Research Database found that the 41 patients with SLE were 2.67 times more likely to experience an acute MI than their controls after correcting for the presence of traditional risk factors. However, the odds ratio for CV events increased to 18.24 (95% CI 1.48 to 225) in patients with SLE and dyslipidaemia. The factors that might have accounted for the excess CV risk included early menopause, impaired renal function, hypercholesterolaemia and hyperhomocysteinaemia (Fischer et al. 2004).

One study found that patients with SLE with coronary artery calcifications were older and had a higher prevalence of conventional CV risk factors than their counterparts without calcifications. Coronary artery calcifications were also associated with hyperhomocysteinaemia, renal impairment and longer disease duration. The Study of Lupus Vascular and Bone Long-Term Endpoints involved a cohort of 149 cases and 124 controls, and showed that greater disease-related damage at the first study visit (as measured by the modified systemic damage index) may predict an increased risk of coronary artery calcium progression, whereas greater disease activity at the first study visit (as measured by hypocomplementaemia and use of glucocorticoids) may predict an increased risk of aorta calcium progression (Lertratanakul et al. 2014).

The published data for smoking are contradictory but, as in the general population, smoking is related to an increased presence of plaques.

Insulin resistance is a well-established CV risk factor in the general population, and has been documented in patients with SLE. However, it is not associated with disease activity, or past or current glucocorticoid treatment, although it does correlate with high C-reactive protein levels. The excess CV risk in patients with SLE may be at least partially related to insulin resistance, which may in turn be due to chronic inflammation (Skaggs et al. 2012*). Also, SLE damage accumulated overtime contributes to insulin resistance in an independent way (Sánchez-Pérez et al. 2017).

A recent meta-analysis of 17 187 patients followed up for a median of 8 years showed that 25.4% experienced a CV event (MI in 4.1% and stroke in 7.3%). The most important predictors were: OR (95%CI) male gender 6.2 (1.49 – 25), hyperlipidaemia 3.9 (1.57 – 9.71), a family history of cardiac disease 3.6 (1.15 – 11.32), hypertension 3.5 (1.65 – 7.54) and SLE-related features such as the presence of autoantibodies 5.8 (3.28 – 7.78) and neurological disorders 5.2 (2.0 – 13.9), whereas there was low correlation with organ damage 1.4 (1.09 – 4.44), SLE activity 1.2 (1.2 – 1.2) or age at the time diagnosis 1.1 (1.07 – 1.17). These findings are important for patient management as they may help to reduce negative outcomes (Ballocca et al. 2015).

2.4.3.1 Lipid profiles and proinflammatory HDL

Lipid profile abnormalities in patients with SLE include low HDL-C, and high VLDL and triglyceride levels. Changes in the structure of the lipoprotein particles seem to contribute to higher atherosclerotic risk (Giannelou and Mavragani 2017*). Dysfunctional proinflammatory HDLs occur in ~50% of patients with SLE (compared to 5–7% of healthy controls), and lead to an approximately 17-fold increase in the risk of carotid plaque (Matsuura et al. 2014).

2.4.3.2 Antiphospholipid antibodies

Most anticardiolipin antibodies target the self-antigen β 2 –glycoprotein I (β 2 GPI), large amounts of which are found in the subendothelial region and at the intima–media junction of atheroma plaque specimens removed during endarterectomy. B2GPI co-localises with CD4+ T cells and may be the target of an autoimmune response that promotes the formation of atheromatous plaque. Antibodies to β 2 GPI increase oxidised LDL capture by macrophages, which is one of the steps in plaque formation.

Clinical studies have led to conflicting results: one study found that increased IMT correlated with the presence of lupus antibodies, but another found that the presence of atheromatous plaque did not correlate with the presence of anticardiolipin antibodies or circulating anticoagulant. A prospective study of 380 patients with SLE found a close correlation between a history of thrombosis and the presence of anticardiolipin antibodies or lupus anticoagulant, but neither of these was associated with IMT, or with the presence of carotid plaque or coronary artery calcifications (Veres et al. 2004; Matsuura et al. 2014).

2.5 Antirheumatic treatment and cardiovascular risk

2.5.1 Acetaminophen (Paracetamol)

Despite previous studies that hinted on a potential association between acetaminophen and CVD risk, more recent data from large databases confirm the lack of a relationship between the use of acetaminophen and IHD or stroke. This renders the drug useful and safe in pain management of patients with CV comorbidity and/or risk factors (Fanelli et al. 2017).

2.5.2 Glucocorticoids (GCs)

The place of GCs is a matter of continuing debate because of their CV side effects—namely, hypertension, dyslipidaemia, insulin resistance and diabetes. However, these side effects are particularly associated with prolonged and high-dose exposure, as shown in a study of RA patients with long term follow-up. The CV risk was associated with glucocorticoid exposure (HR = 1.68, 95% CI 1.14 to 2.47), and increased with higher current (HR per 5 mg increase 1.14, 95% CI 1.05 to 1.24) and cumulative dose (HR per 1 g increase 1.06, 95% CI 1.02 to 1.10) (Avina-Zubieta et al. 2013). Moreover, long term exposure even to medium dose corticosteroids was associated with hypertension in RA patients (Panoulas et al. 2008b), but not with the presence of metabolic syndrome (Toms et al. 2008). On the other hand, GCs rapidly and effectively suppress inflammation in RA and their use might be justified for short-term treatment and at the lowest possible dose—for example, as a ‘bridging treatment’ between the start of, and response to, DMARD treatment. In a recent EULAR task force publication, it is recognised that GCs association with CVD risk might partly be explained by confounding by indication as patients with high disease activity are more likely to be treated with them. Furthermore, risk of harm with GC exposure was considered high for doses >10mg/day, uncertain for 5-10mg/day and low for <5mg/day, with caution advised for the high risk CVD patients even at the low dose (Strehl et al. 2016*).

Similarly in SLE, glucocorticoid treatment may promote the development of atheroma as a result of its deleterious effects on lipid metabolism, blood pressure and glucose metabolism, but it can also reduce the CVD risk by controlling the inflammatory process. The risk may be once again dose-related, as doses of >10 mg/day have been associated with increases in TC, apoB and triglycerides. Two studies have found a significant association between glucocorticoid exposure and CV risk, and a third showed a lower prevalence of carotid plaque in patients less exposed to glucocorticoids or who had not received cyclophosphamide (Skaggs et al. 2012*).

2.5.3 NSAIDs and COXIBs

Despite the relative decrease of the use of NSAIDs/Coxibs for RA, their role in symptomatic management remains important. However, their use has been associated with increased CVD risk in the general population.

A recent study on a large population concluded that moderate doses of celecoxib were not linked to higher CVD risk compared to ibuprofen and naproxen, while the risk of GI bleeding was lower (Nissen et al. 2016).

The field in RA patients remains controversial. A Danish longitudinal cohort study has shown a statistically significantly lower CV risk associated with overall NSAID use (HR 1.22 (1.09-1.37) vs 1.51 (1.36-1.66); $p < 0.01$), whereas the use of rofecoxib (1.57 (1.16-2.12)) and diclofenac (1.35 (1.11-1.64)) was associated with an increased CV risk in patients with RA (Lindhardsen et al. 2014). A recent meta-analysis of more than 15 large trials aimed at determining the CV risk associated with the use of NSAIDs in patients with RA, psoriasis or PsA found that the RR (95% CI) of all-CV morbidity in patients treated with all NSAIDs, COX-2 inhibitors or non-coxib NSAIDs was respectively 1.18 (1.01 – 1.38), 1.36 (1.10 – 1.67) and 1.08 (0.94 – 1.24), and the RR (95% CI) of MI, stroke and major CV events (MACE) was respectively 1.13 (0.93 – 1.37), 2.15 (1.19 – 3.87) and 1.56 (0.82 – 2.97), suggesting that NSAIDs, especially coxibs, increase the risk of all types of CV morbidity (Roubille et al. 2015*). Furthermore, a population based study suggested a protective effect of traditional NSAID use on vascular mortality in AS patients above 65 years of age. Coxibs were not associated with an increased risk for vascular mortality (Haroon et al. 2015).

As there are no clear data on the safety of NSAID use in patients with rheumatic diseases and comorbidities, the use of NSAIDs should be assessed individually on the basis of the indication for pain relief and the risk factors associated with adverse effects. The recent EULAR recommendations advocate their use with caution in RA and PsA patients with documented CVD or presence of risk factors (Agca et al. 2017*). As for AS, NSAIDs hold their place as first-line treatment, but still individual assessment of balance between expected clinical benefit and CVD risk is needed (van der Heijde et al. 2017).

2.5.4 DMARDs

The QUEST-RA trial identified a reduction on the risk of CV morbidity with prolonged exposure to several DMARDs, including MTX, leflunomide and sulfasalazine (Naranjo et al. 2008). Increasing evidence suggests that effective suppression of inflammation lowers the risk of CVD (Micha et al. 2011). In a prospective study of 1240 patients with RA, where 190 died during the 18-year follow-up period, CV mortality was 70% less in the patients receiving MTX than in those not receiving the drug. Another study has shown that patients who fail to respond to MTX have a poor prognosis. Roubille et al. (2015*) published a meta-analysis of observational and randomized controlled trials indicating a reduction of RR for all CV events, MI and CHF (but not stroke or MACEs) in RA patients treated with MTX. It has also been shown that MTX, unlike other DMARDs, associates with reduced propensity of metabolic syndrome (Toms et al. 2009). A recent study proposed that MTX specifically protects the vascular endothelium against inflammatory injury via induction of AMPK- regulated protective genes (Thornton et al. 2016).

Others studies have investigated the effects of DMARDs on CV risk factors, such as diabetes, metabolic syndrome and dyslipidaemia. Both leflunomide and cyclosporine can induce high blood pressure, and should therefore not be considered the DMARDs of first choice in patients with hypertension or at increased CV risk. Cyclosporine has also been associated with increased susceptibility to atherosclerosis and the development of hyperlipidaemia. The use of hydroxychloroquine in RA has been associated with improved lipid and glucose profiles, anti-thrombotic effects, and protection against the onset of atherosclerosis. Finally, sulfasalazine is not the optimal anti-inflammatory agent in patients with CVD, but no studies are available concerning its use in patients with RA and CV involvement (Atzeni et al. 2010).

2.5.5 TNF-inhibitors

Given the important role of TNF in the aetiology of atherosclerosis, one would expect that TNF blockade would lower the risk of CVD risk (Szekanecz et al. 2009*). An American retrospective cohort showed that the use of TNF inhibitors is associated with a lower risk of CV events in patients with RA than the use of DMARDs (Bili et al. 2014) and this was recently confirmed from data from the largest British biologics registry that showed decreased risk for MI for TNF inhibitor compared to synthetic DMARD treatment (Low et al. 2016).

Furthermore, in the aforementioned meta-analysis (Roubille et al. 2015*), TNF inhibition was significantly associated with a reduction in the risk (RR; 95% CI) of all CVDs (0.70; 0.54 - 0.90), as well as in MI (0.59; 0.36 - 0.97), strokes (0.57; 0.35 - 0.92) and major adverse cardiac events (0.30; 0.15 - 0.57), while no significant effect was observed on CHF. Taken together, the published findings suggest that TNF blockers have favourable effects on the risk of CVD in RA. However, despite the findings of the meta-analysis, the lack of suitable prospective, controlled studies prevents any definite conclusions (Tam et al. 2014).

A recent meta-analysis of available studies revealed similar benefits from TNF inhibition in psoriasis and PsA, as it was associated with lower risk for CV events and MI in particular, compared both to topical and to methotrexate treatment. Also, a trend towards lower mortality was identified (Yang et al. 2016).

The potentially favourable effect of TNF blockers on CV risk might be due to attenuated IMT progression (or even a reduction in IMT) because of the similarities in the underlying inflammatory processes of RA and atherosclerosis. The few studies that have investigated the effect of TNF blockade on IMT in patients with RA indicate no progression or even regression of the IMT, but these involved small numbers of patients and had suboptimal methodological designs. The effect of anti-TNF drugs on arterial stiffness was evaluated by means of pulse wave velocity and the augmentation index, and showed, despite the limitations of the studies, that the balance of evidence suggested that TNF antagonists might have a beneficial effect on arterial stiffness and therefore CV risk (Dulai et al. 2012). The findings of a recent study suggest that the beneficial effect of TNF inhibition on arterial stiffness may be independent of its effect on disease activity (Vassilopoulos et al. 2015).

Also, RA patients on TNF inhibitors exhibited a 37% lower adjusted rate of progression of cIMT after a follow up of 3.2 ± 0.3 years (Giles et al. 2011).

TNF inhibitors are probably effective in preventing or even reversing the progression of IMT in patients with AS or PsA who respond to treatment. A prospective study with a median follow-up of 4.9 years found that carotid IMT progressed more slowly in 56 AS patients who continued treatment with anti- TNF drugs than in nine who discontinued anti-TNF treatment (van Sijl et al. 2015).

Furthermore, long-term anti-TNF treatment is associated with increased HDL and TC levels, low LDL levels and an unchanged atherogenic index (Chen et al. 2015*; Provan et al. 2015; Souto et al. 2015; Charles-Schoeman et al. 2016a*). After long-term treatment, triglyceride levels increased and apoB/A levels decreased. The presumed cardioprotective effects of anti-TNF in RA do not seem to be explained by quantitative lipid changes since long-term treatment has no effect on LDL levels or the atherogenic index. Increased HDL levels may have some beneficial effects, but this needs to be confirmed by prospective studies with long-term follow-up (Daïen et al. 2012). Adalimumab has been shown to improve HDL cholesterol efflux capacity (CEC), reduce cholesterol loading capacity (CLC) and inhibits macrophage cholesterol uptake, and infliximab may also restore impaired CEC in RA patients (Voloshyna et al. 2014). A recent meta-analysis has shown that anti-TNF therapy improves insulin sensitivity as indicated by a reduction in HOMA (Burska et al. 2015), however, there is evidence to suggest that this is not so in obese RA patients (Stavropoulos-Kalinoglou et al. 2012).

2.5.6 Tocilizumab, abatacept and rituximab

IL-6 inhibition has been shown to increase TC, LDL-C and TGs, without changing the atherogenic index and interestingly exhibiting lower Lp(a) levels compared to no biological therapy (Chen et al. 2015*; García-Gómez et al. 2017). Despite these changes and possibly through control of inflammatory pathways, tocilizumab has beneficial effects on endothelial function, as measured by FMD, and on arterial stiffness, as measured by PWV. This effect seems to appear very early in treatment with tocilizumab (Provan et al. 2015; Bacchiega et al. 2017).

Rituximab (RTX), a B lymphocyte-depleting drug, and abatacept (ABA), a selective T lymphocyte costimulation modulator, are both very effective at reducing inflammation and may therefore reduce the risk of CVD in patients with RA who respond to treatment. RTX was found to have beneficial effects on the lipid profile of RA patients, as it reduced the atherogenic index after 6 months of treatment and altered the composition of HDL-C to less atherogenic and proinflammatory (Rateman et al. 2013). A study has also shown that RTX reduces the progression of accelerated atherosclerosis in patients with RA, as measured by the improvement in the percentage FMD and the decrease in common carotid IMT (Benucci et al. 2013). In another recent study, rituximab reduced ccIMT and this was accompanied by decreased disease activity and CRP levels (Novikova et al. 2016).

Data for ABA remain scarce and conflicting. In a small report, trends for higher TC, LDL-C and HDL-C with lower atherogenic index were identified, but arterial stiffness by PWV increased after 6 months of treatment. A possible explanation lies to an insufficient decrease in disease activity and systemic inflammation (Mathieu et al. 2013). A recent study of insurance database data found that elderly RA patients treated with abatacept are at lower risk of developing MI than those treated with anti-TNF drugs (Zhang et al. 2016*).

2.5.7 Other biologics

The JAK inhibitor tofacitinib has been approved for the treatment of RA in a number of countries. Like tocilizumab, tofacitinib greatly increases the levels of LDL-C (19-21%) and HDL-C (11-14%), but improves cholesterol ester catabolism and markers of antiatherogenic HDL function. Data from clinical studies and databases do not, at this stage, suggest an increased CV risk in RA patients (Charles-Schoeman et al. 2015, 2016b; Souto et al. 2015).

Published data on newer biologics remain scarce. The use of anti IL-17A agents (secukinumab and ixekizumab) in clinical trials have not identified any safety signals relating to cardiovascular events. The rate of MACEs with these agents was low and comparable to that of TNF-inhibitors in a recent meta-analysis in patients with psoriasis (Rungapiromnan et al. 2017). There are no available data on belimumab, a B-lymphocyte stimulator (BLyS) inhibitor recently licensed for use in SLE.

Table 5 concentrates on the cardiovascular effects of synthetic and biologic DMARDs.

2.6 Cardiovascular risk management

CV risk in patients with inflammatory arthritis is about twice that seen in the general population and, in patients with RA, seems to be similar to that of type 2 diabetes, a well-established CV risk factor. Traditional CV risk factors only partially explain the excess CV risk and another important factor seems to be the inflammatory process (Table 6 and figure 5). RA, AS and PsA should therefore be seen as new, independent CV risk factors requiring appropriate CV risk management and this is recognised in the recent 2016 guidelines of the European Society of Cardiology (Piepoli et al. 2016). However, the ideal actions to ensure proper CV risk management in inflammatory arthritis remain an area of controversy.

Table 5. Cardiovascular effects of biological and non-biological antirheumatic drugs (published on the book 'The heart in Autoimmune Rheumatic diseases' second edition edited by F. Atzeni, A. Doria, M. Nurmohamed, P. Paoletto, Elsevier 2016, Chapter 20, Cardiac Effect of antirheumatic drugs, S Szekanecz)

Drug	Preclinical	Clinical
NSAIDs		↑ Increased CV risk ↑ Hypertension ↑ Heart failure ↑ Arrhythmias
Corticosteroids		↑ CV risk ↑ Hypertension ↑ Hyperglycaemia. diabetes ↑ Heart failure ↑ Arrhythmias
Antimalarials		↓ CV risk ↑ conduction disorders
Sulfasalazine		↑ Thrombocytopenia
Methotrexate	↓ atherosclerosis in rabbits	↓ CV risk ↑ hypotension ↑ pericarditis
Leflunomide		↑ Hypertension
Cyclosporine A		↑ Hypertension
TNF-α blockers	↓ atherosclerosis in mice, rabbits	↓ CV risk ↓ insulin resistance ↓ platelet activation ↓ endothelial cell adhesion molecules ↑ heart failure (NYHA III-IV) ↑ dyslipidaemia ↑ hypertension ↑ infusion-related (if intravenous)
Rituximab	↓ atherosclerosis in mice	↑ infusion-related
Tocilizumab		↑ dyslipidaemia ↑ infusion-related
Abatacept	↓ atherosclerosis in mice ↓ blood pressure in mice	↑ hypertension ↑ infusion-related
Canakinumab	↓ atherosclerosis in mice	↑ endothelial function ↓ pro-atherogenic biomarkers
Tofacitinib		↑ dyslipidaemia

Table 6 Cardiovascular risk factors in inflammatory arthritis

MODIFIABLE RISK FACTORS	NON-MODIFIABLE RISK FACTORS
Traditional risk factors (Smoking, arterial hypertension, obesity, dyslipidaemia, insulin resistance/diabetes)	Age
Surrogate risk factors (Physical inactivity, stress, depression, hypothyroidism, hyperhomocysteinemia, kidney disease)	Sex
Inflammation	Family history
Medication effects (NSAIDs, glucocorticoids, DMARDs)	Genetic polymorphisms

2.6.1 Lifestyle modifications

Increasing patients' awareness for the CV risk associated with their disease should be the cornerstone of CV risk management. Patient and allied health professional educational programs should be implemented to increase volition to behavioural change (John et al. 2011, 2013). Patients should be advised to quit smoking and provided with the opportunity to attend smoking cessation programs. Regular exercise and other modifications to avoid sedentary behaviour (Fenton et al. 2017) are highly recommended in the light of recent data showing their ability to reduce long term inflammation and improve both macro- and micro-vascular function (Metsios et al. 2014*). There is also a strong effect of exercise on reducing other traditional risk

factors (Stavropoulos-Kalinoglou et al. 2013*). Although there are no specific data on a positive effect of dietary modifications on the CV risk related to inflammatory arthritis, a Mediterranean diet (high consumption of fruit, vegetables, legumes, cereals, olive oil and fish) has been shown to reduce CVD in the general population and may have a positive effect on disease activity. Avoidance of excessive alcohol intake, weight control and psychological stress also provide significant benefit.

2.6.2 Control of traditional/modifiable risk factors

Arterial hypertension and dyslipidaemia are major CVD risk factors of multifactorial origin, are underdiagnosed and undertreated in rheumatic diseases and do not have specific treatment targets for these populations. Thus, blood pressure control should follow the management recommendations for the general population. Older studies have indicated that ACE inhibitors and angiotensin II (ATII) receptor blockers should be the preferred treatment choice for RA patients mainly because of their modest anti-inflammatory properties. In view of the lack of newer data, EULAR preferred to omit this preference in its recent recommendations.

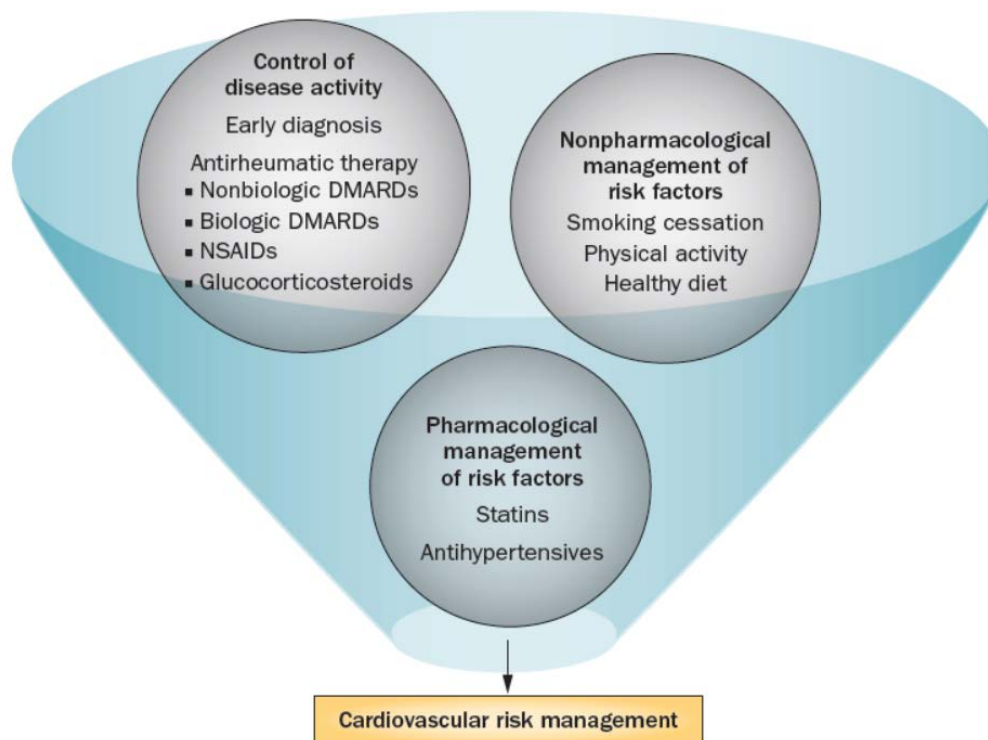

Observational studies suggest that lipid lowering agents, such as statins, associate with reduced cholesterol levels, atherosclerotic burden and CV morbidity and mortality in RA (Schoenfeld et al. 2015), AS and PsA (Rollefstad et al. 2013; Oza et al. 2017). Long-term lipid lowering treatment with rosuvastatin on patients with inflammatory joint disease and established atherosclerosis improved both arterial stiffness and carotid plaque size (Rollefstad et al. 2015). Statins are also considered to have pleiotropic anti-inflammatory properties which may confer additional benefit in patients with inflammatory arthritis (Lv et al. 2015), although this is disputed. Current evidence suggests that statin initiation in these conditions should follow the same guidance as in the general population. In SLE, data are more controversial. Atorvastatin did not show improvement in subclinical atherosclerosis measures (coronary artery calcification, cIMT) or disease activity (SLEDAI) after 2 years of treatment in the Lupus Atherosclerosis Prevention Study (LAPS), an RCT of 200 patients (Petri et al. 2011). On the other hand, statins have been found to improve endothelium-dependent vasodilation by FMD and resting brachial artery diameter (Ferreira et al. 2007) and PWV (Castejon et al. 2017) in SLE patients. Finally, in a recent retrospective cohort of Taiwanese SLE patients with hyperlipidaemia, statin treatment was shown to be associated with decreased mortality, CVD and end stage renal disease (ESRD) (Yu et al. 2015). Despite the inconsistencies, there is a reasonable basis to recommend lipid lowering treatment for CVD risk reduction in SLE in a similar fashion as with RA.

Because of the detrimental effects of insulin resistance and diabetes mellitus and their increased risk in RA patients (Ozen et al. 2016), screening for these co-morbidities with serum glucose and glucose tolerance tests should also be considered.

2.6.3. Control of inflammation

Systemic inflammation is closely associated with atherosclerosis and increased CVD risk. There is increasing literature to support the beneficial role of decreasing the inflammatory burden in patients with inflammatory joint disease with the use of synthetic and biologic DMARDs (Agca et al. 2017*). It seems that low disease activity slows down or improves atherosclerosis regardless of the antirheumatic treatment used (Arida et al. 2017).

Figure 6 Principles of cardiovascular risk management by rheumatologists (Reprinted with permission from Nurmohamed MT et al, Nat Rev Rheumatol. 2015 Aug;11(12):693-704)

In general, CVD risk management in patients with RA (figure 6) should represent an interdisciplinary task involving cardiology, rheumatology and primary care and ensure adequate involvement of the patient as well as effective communication between the managing physicians (Semb et al. 2014*).

Box 1 EULAR recommendations for cardiovascular risk management (Agca et al. 2017*)

OVERARCHING PRINCIPLES

- A. Clinicians should be aware of the higher risk for CVD in patients with RA compared with the general population. This may also apply to AS and PsA.
- B. The rheumatologist is responsible for CVD risk management in patients with RA and other IJD.
- C. The use of NSAIDs and corticosteroids should be in accordance with treatment-specific recommendations from EULAR and ASAS

RECOMMENDATIONS

1. Disease activity should be controlled optimally in order to lower CVD risk in all patients with RA, AS or PsA.
2. CVD risk assessment is recommended for all patients with RA, AS or PsA at least once every 5 years and should be reconsidered following major changes in antirheumatic therapy.
3. CVD risk estimation for patients with RA, AS or PsA should be performed according to national guidelines and the SCORE CVD risk prediction model should be used if no national guideline is available
4. TC and HDLc should be used in CVD risk assessment in RA, AS and PsA and lipids should ideally be measured when disease activity is stable or in remission. Non-fasting lipids measurements are also perfectly acceptable
5. CVD risk prediction models should be adapted for patients with RA by a 1.5 multiplication factor, if this is not already included in the model
6. Screening for asymptomatic atherosclerotic plaques by use of carotid ultrasound may be considered as part of the CVD risk evaluation in patients with RA
7. Lifestyle recommendations should emphasise the benefits of a healthy diet, regular exercise and smoking cessation for all patients
8. CVD risk management should be carried out according to national guidelines in RA, AS or PsA, antihypertensives and statins may be used as in the general population
9. Prescription of NSAIDs in RA and PsA should be with caution, especially for patients with documented CVD or in the presence of CVD risk factors
10. Corticosteroids: for prolonged treatment, the glucocorticoid dosage should be kept to a minimum and a glucocorticoid taper should be attempted in case of remission or low disease activity; the reasons to continue glucocorticoid therapy should be regularly checked

SUMMARY POINTS

- Patients with inflammatory arthritis (rheumatoid arthritis (RA), ankylosing spondylitis (AS) or psoriatic arthritis (PsA)) should be considered as having approximately twice the risk for cardiovascular disease (CVD) as that observed in the general population. Patients with systemic lupus erythematosus (SLE) should be considered as being at very high risk for CVD.
- RA, AS, PsA and SLE should be acknowledged as new, independent cardiovascular (CV) risk factors.
- Traditional CV risk factors may be increased in patients with inflammatory arthritis or SLE.
- The inflammatory process significantly contributes to the increased CVD risk.
- Effective treatment with synthetic or biologic disease-modifying antirheumatic drugs reduces the risk of CVD in patients with inflammatory arthritis.
- Regular CV risk screening is required for patients with inflammatory arthritis or SLE.
- CV risk management, if necessary, should be part of routine care in these patient groups.
- CV risk management entails lifestyle modification, tight disease control and CV risk factor management to predetermined targets.

3 Anaemia: pathophysiology, diagnosis and treatment

LEARNING OBJECTIVES

- Describe the most important mechanisms underlying pathophysiology of anaemia associated with chronic inflammation
- Establish the diagnosis of inflammatory anaemia based on clinical history, differential diagnosis, interpretation of laboratory values
- Treat anaemia according to aetiology and the underlying rheumatic disease

3.1 Introduction

Chronic anaemia may occur in various inflammatory situations, malignancies and infectious diseases (table 7). Anaemia of chronic disease (ACD) is the second most prevalent cause of anaemia after iron deficiency anaemia (IDA). It has been associated with disease activity, fatigue and physical disability in patients with arthritis (Han et al. 2007). Its prevalence varies greatly among different rheumatic diseases, probably because of pathophysiological differences, comorbid aggravating factors, genetic predisposition and treatment effects. It ranges between 33 and 60% for RA and >50% for SLE (Wilson et al. 2004; Weiss and Schett 2013*; Keel and Abkowitz, 2009*).

Table 7 Anaemia associated with chronic diseases

Disease	Estimated prevalence (%)
Inflammatory diseases	8–71
Rheumatoid arthritis	
Systemic lupus erythematosus	
Vasculitis	
Sarcoidosis	
Inflammatory bowel disease	
Acute and chronic infections	18–95
Malignancies	30–77
Haematological	
Solid	
Chronic renal failure	23–50

Figure 7 Chronic inflammation leads to anaemia by the production of proinflammatory cytokines. Among these cytokines, tumour necrosis factor α (TNF α), interferon γ (IFN γ) and transforming growth factor β (TGF β) inhibit erythropoiesis and the release of erythropoietin (EPO) from the kidney. Interleukin 6 (IL-6) stimulates the production of hepcidin by hepatocytes, which leads to the inhibition of iron absorption and iron release by macrophages.

3.2 Pathophysiology of chronic anaemia

ACD is a multifactorial immune-driven process, characterised by changes in iron homeostasis, impaired erythroid progenitor proliferation, reduced biological activity of erythropoietin (EPO) and reduced erythrocyte life cycle (Weiss and Goodnough 2005*).

3.2.1 Effects of proinflammatory cytokines on early haematopoiesis and erythropoiesis

TNF α and transforming growth factor β (TGF β), in synergism with IFN γ , inhibit the proliferation of haematopoietic progenitor cells, the self-renewal capacity of multipotent stem cells and induce Fas/Fas ligand-dependent apoptosis (Figure 7). In RA, TNF α and IFN γ also inhibit burst-forming unit-erythroid (BFU-E) and colony-forming unit-erythroid (CFU-E) colony formation and their effect is negated by DMARD treatment (Doyle et al. 2009). Erythroid progenitors express various death receptors so their exposure to death receptor ligands, including TNF α , Fas ligand or TRAIL, during inflammation results in disturbed erythropoiesis. In inflammatory diseases, the extent of anaemia correlates with circulating proinflammatory cytokine levels.

Proinflammatory cytokines also inhibit erythropoiesis indirectly, by suppressing the synthesis of EPO protein and mRNA synthesis (figure 7). There is impaired response to EPO in ACD associated with RA and SLE, where anti-EPO autoantibodies may also play a role (Voulgari et al. 1999; Giannouli et al. 2006*; Theurl et al. 2006).

3.2.2 Effects of IL-6 on the hepcidin system and iron homoeostasis

Another important mechanism of ACD is the IL-6–hepcidin axis that is involved in iron homoeostasis. Hepcidin, also known as LEAP-1 (liver-expressed antimicrobial peptide), is a 20–25 amino acid antimicrobial peptide that regulates iron homoeostasis by binding to and blocking ferroportin, the main cellular iron export protein. Increased expression of hepcidin results in inhibition of ferroportin-mediated transfer of dietary iron from duodenal enterocytes to the circulation and blockage of iron export from macrophages to be used for erythropoiesis. The expression of hepcidin is induced by inflammatory mediators (mainly IL-1, IL-6 or IL-22). Other cytokines, such as TNF α and IFN γ have similar effects on a hepcidin-independent manner. Thus, the combined action of hepcidin and cytokines leads to hypoferraemia and restricted availability of iron for erythropoiesis, which is the consequence of reduced dietary iron absorption and iron retention in macrophages, the latter reflected by increased ferritin levels.

Among proinflammatory cytokines, IL-6 (but not TNF α) induces hepatic synthesis of hepcidin, while hypoxia and anaemia downregulate hepcidin release. (Nemeth et al. 2004; Singh et al. 2011; Weiss and Schett 2013*).

3.2.3 Iron deficiency

Even though in ACD there usually is abundance of iron supply (which, however, is pathologically unavailable for haemopoiesis), there are several occasions where actual iron deficiency may occur. Menstruation is the commonest cause for IDA in the general population and the majority of RA and SLE patients are women. Acute or chronic gastrointestinal blood loss may accompany rheumatic diseases on account of underlying disease (eg. bowel inflammation) or treatment side effects (eg. glucocorticoids, NSAIDs). Furthermore, diseases that are frequently encountered as comorbidities in rheumatic diseases, such as autoimmune gastritis, *Helicobacter pylori* infection and coeliac disease, may also contribute to IDA (Hershko et al. 2005). Finally, although a rare cause of significant IDA, decreased dietary iron intake should always be considered.

3.2.4 Other vitamin deficiencies

The development of anaemia attributable exclusively to vitamin B12 or folic acid deficiency is rare, but deficiency of these vitamins can contribute to an extent to the anaemia of the rheumatic patient. Pernicious anaemia, a common autoimmune cause for vitamin B12 deficiency, is frequent in several autoimmune rheumatic conditions. In a mixed rheumatic disease population study with a 35–49% prevalence of anaemia, up to 24% of patients had vitamin B12 deficiency, although not all had anaemia (Segal et al. 2004). Low levels of serum folic acid were rare in the same study, but they may be seen with DMARD treatment that antagonises

folic acid metabolism (MTX, sulfasalazine, azathioprine), especially if there is no folic acid supplementation used, and should always be in the differential diagnosis. The aforementioned DMARD agents can cause macrocytosis, even in the absence of anaemia. This may disguise the expected microcytosis of iron deficiency or the normal indices of anaemia of chronic disease.

3.2.5 Treatment related factors

Several antirheumatic and immunosuppressive drugs (MTX, azathioprine, leflunomide, cyclosporine, mycophenolate) and adjunct treatments (NSAIDs, proton pump inhibitors, urate lowering drugs) can negatively affect erythropoiesis and decrease red blood cell half-life. Some of the newer DMARDs, in particular the Janus Kinase (JAK) inhibitors, exert a direct negative effect on EPO through JAK2 inhibition, which is an essential downstream signal component of the EPO receptor and, thus, cause mild anaemia through this unique mechanism. However, this seems to have only weak effect on fatigue and quality of life (Schulze-Koops et al. 2017).

3.2.6 Disease related factors

Besides chronic inflammation, several other causes of anaemia can be encountered in rheumatic diseases. In SLE, haemolysis may develop in up to 10% of patients during the disease and is more frequent in African American ethnicity and with the use of azathioprine (Durán et al. 2008). Pure red cell aplasia can also be seen in SLE, driven by IgG autoantibodies, but also in parvovirus B19 infection which may present as symmetric polyarthrititis. Macrophage activation (haemophagocytic) syndrome, caused by uncontrolled activation and proliferation of macrophages and T-cells, may complicate JIA, AOSD and SLE and is a rare cause of anaemia.

3.3 Differential diagnosis of chronic anaemia

ACI is usually normocytic-normochromic (normal MCV and MCH) and less frequently hypochromic – microcytic. Serum iron concentration and transferrin saturation (percentage of transferrin loaded with iron) are low, but these also characterise IDA. The distinguishing features lie in the ferritin concentration (high in ACI, but low in IDA) and the circulating transferrin levels (low in ACI, normal to high in IDA). In the complicated occasion where there is ACI with concomitant iron deficiency, other parameters to distinguish the two types of anaemia include serum soluble transferrin receptor (sTfR) or, even more accurate, the ratio sTfR:log ferritin (table 8) (Skikne et al. 2011; Weiss and Schett 2013*).

Table 8 Differential diagnosis of chronic inflammatory anaemia

Iron biomarkers	Inflammatory anaemia	Iron-deficiency anaemia	Combination
Serum iron	↓	↓	↓
Transferrin	N or ↓	↑	↓
Transferrin saturation	↓	↓	↓
Soluble transferrin receptor (sTfR)	N	↑	N or ↑
Ferritin	N or ↑	↓	N or ↓
sTfR:log ferritin	<1	>2	

N: normal, log: logarithm.

3.3 Treatment

3.3.1 Treatment of the underlying inflammatory disease

In chronic inflammatory diseases, such as arthritis, the degree of anaemia correlates with disease activity. Therefore, the underlying condition should be treated and disease activity suppressed. Glucocorticoid treatment reverses ACI in patients with giant cell arteritis and polymyalgia rheumatica. TNF α inhibitors improve anaemia in patients with RA. For example, administration of infliximab resulted in increasing haemoglobin and decreasing IL-6 levels. Infliximab also restored impaired erythropoiesis. Anti-TNF therapy improved postoperative recovery of haemoglobin in patients with RA. Etanercept and adalimumab also increased haemoglobin levels in RA or JIA. As IL-6 is a major stimulator of the hepcidin pathway and anaemia correlates with serum IL-6 levels, the blockade of IL-6 receptor by tocilizumab is also a feasible option for controlling chronic anaemia. Indeed, tocilizumab restored haemoglobin levels in RA and improved anaemia by downregulating hepcidin in Castleman's disease (Davis et al. 1997; Doyle et al. 2009; Isaacs et al. 2013; Song et al. 2013).

3.3.2 Treatment of anaemia

In severe life-threatening cases, blood transfusions should be carried out if necessary but only as emergency treatment.

As rheumatic diseases are most often associated with normocytic–normochromic anaemia and normal soluble transferrin receptor levels (table 7), iron supplementation is rarely needed. If iron deficiency is also present, intravenous iron treatment may be given in the form of iron gluconate or iron sucrose and is probably preferable to oral treatment, as iron enteric absorption is impaired in ACD. Intravenous iron supplementation is needed when transferrin saturation is <20% and ferritin <400 ng/mL. If ferritin is >800 ng/mL or transferrin saturation >50%, no iron supplementation is necessary.

As EPO stimulates erythroid colony growth, there have been few trials using recombinant human EPO to treat chronic anaemia. In a Cochrane meta-analysis, the data supporting the use of EPO-stimulating agents in

increasing haemoglobin and improving quality of life in RA were conflicting and the trials had high risk of bias (Martí-Carvajal et al. 2013).

SUMMARY POINTS

- ➔ Chronic anaemia is common in inflammatory diseases.
- ➔ Chronic inflammatory anaemia is usually normocytic--normochromic, rarely mildly microcytic--hypochromic.
- ➔ Proinflammatory cytokines inhibit early haematopoiesis and erythropoiesis, in part by suppressing the release of erythropoietin (EPO).
- ➔ Interleukin 6 induces hepcidin release by hepatocytes, leading to impaired iron absorption and release by macrophages.
- ➔ Inflammatory anaemia should be distinguished from iron-deficiency anaemia, but the two forms may be associated. Inflammatory anaemia is usually milder.
- ➔ Therapeutic strategies include control of the underlying disease and, if needed, iron and EPO supplementation.

IN-DEPTH DISCUSSION I

Cardiovascular disease risk in rheumatoid arthritis

Introduction

Cardiovascular disease (CVD) is a leading cause of morbidity and mortality in rheumatoid arthritis and it is mainly linked to accelerated atherosclerosis (1). Similar to the general population, increased CVD risk in RA has been associated with “traditional” risk factors, such as smoking, hypertension, dyslipidaemia, diabetes, obesity, physical inactivity) and “novel” risk factors, primarily systemic inflammation (increased high-sensitivity C-reactive protein (hsCRP)) and its sequelae, such as microalbuminuria and renal dysfunction (2). However, the excess CVD risk in RA is only partially explained by the traditional risk factors, which clearly suggests that systemic inflammation, genetic factors and antirheumatic treatment may contribute to it. Common inflammatory pathways for RA and atherosclerosis indicate a shared pathogenetic mechanism (3).

As many of these risk factors are modifiable (4), CVD risk management should be based on a determination of the CVD risk profile for the individual patient. The recent EULAR recommendations for CVD risk management in inflammatory arthritis advocate CVD risk assessment for all patients at least once every 5 years (or earlier if the risk is moderate-to-high) in order to implement lifestyle modification advice and CVD preventive treatment (5).

Primary CVD prevention

RA disease activity control remains the main focus for the rheumatologist and is a cornerstone for CVD risk reduction. Accumulated evidence clearly suggest that reducing the inflammatory burden lowers CVD morbidity and mortality. However, attention to classical CVD risk factors is also of paramount importance.

Patient education and lifestyle modification plays a significant role in CVD risk management in RA. All patients should be advised to quit smoking. Adherence to a healthy (e.g. Mediterranean) diet and weight control is also important. The role of structured exercise and prevention of physical inactivity has been proven and it should also be highlighted to RA patients. Treatment (to target) of arterial hypertension contributes in modifying a major CVD risk factor, which in RA has multiple possible causes and has been both under-recognised and undertreated. Indications for anti-hypertensive medication should follow the national guidelines. Lipid lowering treatment with statins has proven efficacious in reducing the overall atherosclerotic burden and improving CVD mortality in RA and is well-tolerated (5).

Cardiovascular risk prediction algorithms

Decision making for the use of cardio-protective medication should be backed by accurate CVD risk prediction. RA patients should be assigned to low, moderate, high and very high risk categories, using a calculator predicting their 10-year CVD mortality risk. For the general population, there are several such tools available, such as the Reynolds Risk Score (RRS)(6), Framingham Risk Score (FRS)(7) and the 2013 ACC/AHA guidelines

score (8), widely used in the US, the System for Cardiac Operative Risk Evaluation (SCORE) calculator(9), which is widely used in Europe, the QRISK2 calculator(10), which was developed and has been adopted in the UK. The RRS is the only score that includes a measure of inflammation (hsCRP), while only the QRISK2 incorporates RA as an independent risk factor (with a 1.4 multiplication).

However, none of these CVD risk assessment systems has been shown to perform well in patients with RA (11,12), possibly depicting the complex interplay of CVD pathogenesis in rheumatic disease (lipid paradox, presence of systemic inflammation, accelerated atherosclerosis). Thus, in 2009, EULAR recommended the implementation of a 1.5 multiplication factor on the SCORE algorithm in the presence of certain disease characteristics (13). Several other alternative approaches have also been advocated, e.g. to increase the age of an RA patient by 15 years or to add a multiplication factor of 1.4. In the light of the lack of appropriate evidence and also data showing increased CVD risk already in early RA, the 1.5 multiplication factor was retained in the recent updated EULAR recommendations, on this occasion independent of any disease characteristic criteria (5).

Solomon et al. (14) suggested an RA-specific CVD risk algorithm, the Expanded Risk Score for patients with RA (ERS-RA), which, besides traditional risk factors (age, gender, smoking status and presence or absence of hypertension, hyperlipidaemia and diabetes – captured from the physician's report for the diagnosis or the use of relevant medication), utilises measures for disease activity (Clinical Disease Activity Index, CDAI), function (modified Health Assessment Questionnaire, mHAQ), daily prednisolone use and RA disease duration (dichotomised at 10 years). This calculator performed well in a cohort from the CORRONA registry, but did not demonstrate any advantages to other calculators in other cohorts.

Comparison of the variables needed for each CVD risk algorithm is shown in table 1.

Recently, A Trans-Atlantic Cardiovascular Consortium for RA (ATACC-RA) was formed with the task to develop an RA specific CVD risk calculator by pooling resources from 13 centres worldwide. This effort has met significant challenges, because of differences in geographical and population characteristics, management strategies and, possibly, reducing prevalence of CVD in more recent cohorts due to improved disease control and lipid lowering treatments. Neither of the two developed models was demonstrated to have improved performance in RA patients compared to the general population calculators (15). Similarly, the RA specific calculators (QRISK2, SCORE with EULAR 1.5 multiplier, ERS-RA) did not improve CVD risk prediction in comparison with FRS and 2013 ACC/AHA models in a recent study and their clinical utility has become debatable (16).

The role of imaging in primary CVD prevention

Active screening for subclinical atherosclerosis may arguably be a good alternative to CVD risk prediction for primary CVD prevention (17). As both coronary and carotid atherosclerosis are frequent in RA patients, this approach might also be useful in this population. Available screening methods include measurements of coronary artery calcification, endothelial dysfunction and arterial stiffness, but carotid ultrasonography (cUS) looking for carotid plaques (CP) and measuring carotid intima media thickness (cIMT) is gaining ground. RA-specific factors, such as disease duration and activity (as measured by CDAI), have been positively correlated with CP larger size and higher vulnerability (18). The presence of CP has been linked to poor CVD-free survival and higher rate of ischemic heart disease (19), while severe cUS abnormalities (cIMT>0.9mm and/or CP) were observed in 63% of RA patients categorized in moderate CVD risk. A composite model of mSCORE (which includes the EULAR 1.5 multiplier) and severe cUS abnormalities was highly sensitive for high/very high CVD risk (20). EULAR recently recommended considering the use of cUS screening as part of CVD risk evaluation in RA (5). However, the clinical and cost-effectiveness of such a strategy remains to be proven in relevant trials.

Conclusion

Regardless of the difficulties in accurate CVD risk assessment, there is no doubt that adequate preventive management in RA is suboptimal, both in primary (patients in high CVD risk) and secondary (patients with already established CVD) prevention (21). In this context, there is a need to improve CV risk stratification and prediction, but also make sure that rheumatologists are educated with respect to screening and identifying high-risk patients. Educational programs for patients and allied health professionals on RA comorbidity management might be instrumental in facilitating the identification and management of CV risk factors by general practitioners, rheumatologists and cardiologists (22).

IN-DEPTH DISCUSSION II

Current therapies of AA amyloidosis secondary to inflammatory rheumatic diseases

Introduction

Systemic amyloidosis is caused by the misfolding and irreversible transition of amyloid precursor proteins to insoluble fibrils, which cause damage by deposition on various internal organs. Serum amyloid A (SAA) is the amyloid precursor characteristic for AA amyloidosis. High levels of circulating SAA are associated with inflammatory rheumatic diseases. In fact, rheumatoid arthritis (RA), ankylosing spondylitis (AS) and other arthritides account for 70% of all AA amyloidosis cases. The production of SAA is regulated by pro-inflammatory cytokines, such as tumour necrosis factor α (TNF- α), interleukin-1 (IL-1) and IL-6 [1-3].

In AA amyloidosis, amyloid deposition occurs primarily to the kidneys, liver, spleen and gastrointestinal (GI) tract. The predominant feature of amyloidosis at diagnosis is proteinuria and renal failure. Hepatic and splenic deposits rarely lead to clinical manifestations. GI features include malabsorption, pseudo-obstruction, diarrhoea or vomiting secondary to submucosal amyloid infiltration [1-5].

The survival of AA amyloidosis patients has increased from 24 months in 1991 [6] to 79 months by 2008 [7]. Also, recent data confirm both reducing incidence and improved survival in systemic amyloidosis [8, 9], suggesting improved management of inflammatory disease in the era of biologic drugs [10]. Overall, however early referral to a specialist and early treatment are necessary to improve prognosis. Reducing SAA concentrations to lower than 4mg/L has been associated with the best outcomes [10].

Treatment of AA amyloidosis by controlling the underlying disease

In AA amyloidosis secondary to arthritides and autoimmune diseases, the major goal of therapy is to control the underlying disease. Aiming at disease remission or low disease activity will decrease the risk of amyloid deposition and will eventually improve survival [1, 7]

In case reports, traditional disease modifying antirheumatic drugs (DMARDs), such as methotrexate, cyclophosphamide and leflunomide showed some efficacy to decrease circulating SAA levels, however, no large trials have been conducted [1, 2, 5, 7, 11]. High dose colchicine has proven effective in inducing remission in AA amyloidosis caused by Familial Mediterranean Fever [2], but results from its use in rheumatic disease related amyloidosis were not optimistic [12].

Biologic DMARDs have shown outstanding efficacy in arthritides and are also effective in controlling secondary renal and gastrointestinal AA amyloidosis [5, 13]. Among TNF- α inhibitors, etanercept and infliximab decreased proteinuria, improved renal function, reduced acute phase reactants and inhibited gastrointestinal amyloid deposition in arthritis patients [13, 14]. In one study, 15 patients with AA amyloidosis secondary to inflammatory arthritis were treated with infliximab (n=10), etanercept (n=4) or both (n=1). Anti-TNF therapy resulted in dramatic improvement in proteinuria in 3 patients, stabilized it in 5 patients, while amyloidosis

progressed in 7 patients [13]. In a cohort of 14 patients with secondary AA amyloidosis, etanercept treatment resulted in clinical improvement of proteinuria and diarrhoea and reduction of SAA levels [15].

Among other biologics, IL-1 inhibition (mainly through the IL-1 receptor antagonist anakinra) has been introduced to the treatment of AA amyloidosis secondary to auto inflammatory syndromes. These periodic fever syndromes include TNF receptor-associated (TRAPS) and cryopirin-associated periodic syndrome (CAPS), as well as FMF, Muckle-Wells syndrome and familial cold auto inflammatory syndrome (FCAS) [5]. Anakinra has also been proven efficacious in the empirical treatment of AA amyloidosis of uncertain aetiology [16]. Canakinumab, an anti-IL1 β IgG1/k monoclonal antibody, led to clinical and laboratory improvement in similar cases of AA amyloidosis [17].

The IL-6 pathway is also involved in the regulation of SAA production [1] and thus its inhibition was expected to provide significant benefit. The anti-IL-6 receptor antibody tocilizumab successfully controlled AA amyloidosis in patients with RA, juvenile idiopathic arthritis (JIA) and adult onset Still's disease, as well as in non-RA patients (FMF). Tocilizumab improved proteinuria, as well as gastrointestinal amyloid deposition and diarrhoea [2, 5, 18-20]. It may have better results compared to TNF-inhibitors as suggested by a retrospective study looking into disease remission and drug survival but this requires confirmation [21].

There are limited data on the effects of abatacept and rituximab in AA amyloidosis.

Inhibition of fibrillogenesis

Glucosaminoglycan (GAG) chains are universal constituents of amyloid deposits. Thus, inhibition of proteoglycan assembly may block amyloid fibrillogenesis. Indeed, some carbohydrate analogues of N-acetyl glucosamine inhibit the binding between heparan sulfate or the heparin sulfate proteoglycan perlecan and amyloid fibril proteins. In preclinical studies, orally administered low molecular weight anionic sulfonate or sulfated compounds inhibited the development of experimental murine AA amyloidosis. One of these GAG mimetic agents, eprodisate has been introduced to human trials [21, 22]. In a phase II/III clinical trial, the effects of eprodisate were compared to those of placebo in 183 patients with systemic AA amyloidosis. Although the specified primary end point for efficacy was not achieved, eprodisate significantly slowed the progression of renal disease in comparison to placebo. Thus, inhibition of interactions between GAGs and amyloid fibrils by using small molecule GAG mimetics remains a promising therapeutic approach in all types of amyloidosis [1, 2, 22].

Induction of amyloid deposit regression

Although direct induction of amyloid deposit regression has not yet been feasible, there have been attempts to target the serum amyloid P (SAP) component. The non-fibrillar SAP is universally present in amyloid

deposits, persists within these deposits for prolonged periods and it can be identified by SAP scintigraphy [1,5]. Small molecular compounds, as well as antibodies inhibiting the binding of SAP to amyloid fibrils are under investigation. For example, administration of an anti-human-SAP antibody to mice with amyloid deposits containing human SAP triggered a potent, complement-dependent, macrophage-derived giant cell reaction that removed massive visceral amyloid deposits without adverse effects [24]. The antibody has been tested on humans in a proof-of-concept study with promising results [25]. Finally, blocking SAA-transcribing mRNA with antisense oligonucleotides reduced SAA and tissue amyloid burden in murine models [26].

Conclusion

In AA amyloidosis secondary to inflammatory rheumatic diseases, our primary goal is to control the underlying disease. Traditional DMARDs have limited efficacy in AA amyloidosis as no large trials have been conducted with these compounds. The efficacy of TNF inhibitor biologics, primarily etanercept and infliximab, has been increasingly investigated with good results. Anakinra may be administered to patients with amyloidosis secondary to periodic fever (auto-inflammatory) syndromes. IL-6 inhibition by tocilizumab seems to offer significant benefits in controlling SAA production and disease activity. Other mechanisms to reverse amyloidosis include the inhibition of fibrillogenesis by GAG mimetics, such as eprodisate. Small molecule inhibitors of and antibodies to SAP may induce the regression of amyloid deposits.

Part I: Hereditary hemochromatosis

LEARNING OBJECTIVES

- Outline the epidemiology of hereditary haemochromatosis (HH)
- Describe known genetic defects (HFE and non HFE) and their relative frequencies in HH
- Describe the pathogenesis of HH at the tissue, cellular and receptor levels
- Describe the musculoskeletal manifestations of HH
- Describe the other organ-specific manifestations
- Describe and evaluate methods of diagnosing HH, including serological markers of iron stores and genotype testing
- Describe the indications for and management of therapeutic and maintenance phlebotomies in HH
- Describe factors related to prognosis in HH

I. INTRODUCTION.

Haemochromatosis, first described by the French physician Armand Trousseau in 1713, is a hereditary multi-organ disorder due to mutations in genes that control iron metabolism leading to iron overload (Pietrangelo, 2010*). It is characterized by increased iron accumulation in many organs including the liver, heart, joints and endocrine organs. The most severe features of the disease are liver cirrhosis and hepatocarcinoma, diabetes and heart failure. As severe organ failure can be prevented by phlebotomy starting before irreversible damage has occurred, hereditary haemochromatosis (HH) must be recognised early. Since arthralgia, together with fatigue, is one of the earliest features of HH, rheumatologists have an important role to play in the early diagnosis of the disease. Family screening is also very important for its early recognition and treatment. The most common genotype (> 95%) is homozygosity for the p.Cys282Tyr mutation of the HFE gene (MIM 235200) (Feder et al, 1996*). Several other mutations have been described (Brissot and Loréal, 2016*).

II. EPIDEMIOLOGY.

HH is the most common inherited genetic disease in European populations. Classic HH, linked to the HFE gene, is transmitted as an autosomal recessive trait. Population screening has shown that the prevalence of the HFE genotype varies among ethnic groups. In white populations in the USA and Western Europe, the frequency of homozygotes is approximately 4 per 1000 (0.44%), and the frequency of heterozygotes is approximately 100 per 1000 (9.6%) (Adams et al, 2005). The highest reported prevalence of C282Y homozygosity is in Ireland (Gleeson et al, 2004). Lower prevalences are estimated for other ethnic groups. In Native Americans, the frequency of homozygotes is approximately 0.11%, in Mexican Americans 0.027%, in non-Hispanic black people 0.014%, in

Pacific Islanders 0.012% and in Asians 0.00004% (Adams et al, 2005). Such distribution is consistent with a predominantly northern European origin of the mutation (Powell et al, 2016*). It should be stressed that the phenotype penetrance of the C282Y genotype is low, making population screening unsuitable. Longitudinal studies have shown that only 38–50% of homozygous individuals develop raised iron parameters, and only 10–33% eventually develop haemochromatosis-associated morbidity (Whitlock et al, 2006). Because of iron loss through menstrual bleeding and childbirth, the rate of iron accumulation is lower in premenopausal women and clinical penetrance is lower in women. A cohort study showed that at least 28% of male C282Y homozygotes compared with 1% of female C282Y homozygotes developed iron overload-related disease (Allen et al, 2008). Genetic polymorphism, environmental factors such as alcohol misuse, liver steatosis and coexisting viral infection, also seem to modify the risk of developing clinically overt liver disease (van Boven et al, 2011*; Brissot and Loréal, 2016*).

III. GENETICS.

Five genes have a key role in iron metabolism: ferroportin, hepcidin, haemojuveline, caeruleoplasmine and transferrin. The gene defect first described in 1996 as a cause of HH is a G>A mis-sense mutation leading to substitution of tyrosine for cysteine at the 282 amino acid position (C282Y) of the protein product of the HFE gene, located on the short arm of chromosome 6 (Feder et al, 1996*). Another mutation in which aspartic acid is substituted for histidine at position 63 (H63D) His63Asp has also been associated with haemochromatosis. Phenotypic HH may arise when both alleles of chromosome 6 have the C282Y mutation in an homozygous state. In the other cases, iron overload is very rare or there is another associated gene mutation. A C282Y homozygous state has been found in 70–100% of patients with phenotypic HH; approximately 10% are compound heterozygotes (Feder et al, 1996*; Brissot and Loréal, 2016*), but in the population at large, documented iron overload disease has been found to be rare in C282Y/H63D heterozygotes (Gurrin et al, 2009). A small number of patients are either heterozygous for C282Y or homozygous for H63D, but these genotypes do not appear to confer an increased risk of iron overload (Brissot and Loréal, 2016*). Although more than 95% of HH in the white population are associated with HFE gene mutations, other genes have been linked to much rarer forms of the disease, in particular in southern European and non-Caucasian populations (table 1) (Brissot and Loréal, 2016*).

Table 1: Genetic, clinical and laboratory features, and pathogenesis of the various types of hereditary haemochromatosis (HH)

HH type	Gene	inheritance	Typical features	Laboratory findings	Pathogenesis
1	HFE	Autosomal recessive	Caucasian, male, 40-50 years old. Fatigue, arthralgia, liver damage with predominant hepatocyte iron loading. Diabetes, endocrine dysfunction, cardiomyopathy, dark skin	Increased serum ferritin and transferrin saturation	Decreased hepcidin, due to impaired regulation and leading to increased intestinal iron absorption and release of iron from reticuloendothelial cells
2A	Hemojuvelin (HJV)	Autosomal recessive	Caucasian or non-Caucasian, Male or female, 20-40 years old, As for HFE; cardiomyopathy and endocrine disorders are more frequent	Increased serum ferritin and transferrin saturation	Decreased hepcidin, due to loss of regulation, leading to increased intestinal iron absorption and release of iron from reticuloendothelial cells
2B	Hepcidin (HAMP)	Autosomal recessive	Caucasian or non-Caucasian, Male or female, 15-20 years old, As for HFE; cardiomyopathy and endocrine disorders are more frequent	Increased serum ferritin and transferrin saturation	No active hepcidin leading to maximal intestinal iron absorption and release of iron from reticuloendothelial cells
3	Transferrin Receptor 2 (TfR2)	Autosomal recessive	As for HFE	Increased serum ferritin; transferrin saturation may be normal	Decreased hepcidin, due to impaired regulation and leading to increased intestinal iron absorption and release of iron from reticuloendothelial cells
4	Ferroportin (Fpn)	Autosomal dominant	Caucasian or non-Caucasian, Male or female, 10-80 years old, As for HFE, generally milder; liver iron loading frequently predominates to Kupffer cells	Increased serum ferritin and transferrin saturation	Reduced ferroportin iron transport ability, leading to hepcidin resistance and accumulation of iron in reticuloendothelial cells

IV. PATHOGENESIS.

IV.1 Iron Metabolism

Iron is involved in basic cellular functions such as DNA synthesis, cellular respiration and oxygen transport and is mandatory for erythropoiesis (Brissot and Loréal, 2016* Powell et al , 2016*) . The only iron source is alimentary, absorbed in duodenum.. Two-thirds of iron is incorporated into haemoglobin, and the remainder is found in muscle myoglobin, enzymes and cytochromes. Macrophages are involved by recycling iron from erythrocytes. Less than 1% circulates in plasma bound to transferrin. Excess free iron, however, damages tissue by catalysing the production of free-radical oxygen species that attack cell membranes, proteins and DNA.

The master regulator of iron metabolism is the protein hepcidin, a polypeptide hormone which is produced by the liver (Pietrangelo, 2010*; Ganz, 2011*). The plasma hepcidin level is regulated by various stimuli: hypoxia, anaemia and iron deficiency all inhibit hepcidin synthesis. In contrast, hepcidin secretion is induced by infections and inflammation, through inflammatory cytokines, including IL-6. Hepcidin is involved in the pathogenesis of anaemia and hypoferrremia of inflammation (Ganz, 2011*).

Hepcidin acts in connection with ferroportin (FPN), a transmembrane protein that exports iron from the cells. FPN is expressed by cells involved in iron metabolism, including duodenal enterocytes, hepatocytes and reticuloendothelial macrophages. Following interaction with hepcidin, FPN is internalised and degraded, and transfer of iron from the cell into the plasma compartment is impaired (Ganz, 2011*; Brissot and Loréal, 2016*).

IV.2 Mechanisms of HHs

Mutations of the FPN gene are involved in type 4 HFE, linked to an increased iron transport from enterocytes and macrophages into the blood. The other types of HFE are linked to a decrease in hepcidin production (table 1). Type 2B is due to a mutation of the gene coding for hepcidin and results in a very severe form of HH. Type 2A may be explained by the role of haemojuvelin (HJV) in hepcidin secretion control by the BMP-SMAD signalling pathway. BMP6 is held to play an important part in this control, as *bmp6*-null mice exhibit reduced hepcidin expression and tissue iron overload, that is, a haemochromatosis-like phenotype (Andriopoulos et al, 2009; Meynard et al, 2009). In mice, interaction between BMP6 and HJV increases hepcidin expression and reduces levels of iron (Andriopoulos et al, 2009). The human mutation could impair HJV binding to BMP6. Type 3 HH is related to mutations of the *TfR2* gene. *TfR2* is a homolog of *TfR1*, the receptor essential for the uptake of iron transferrin by erythrocytes and expressed in most cells. *TfR2* is primarily expressed in the liver and plays a role in transferrin-induced hepcidin expression. Loss of function is associated with haemochromatosis (Fleming et al,

2002). Interaction between HFE and Tfr2 has been shown to be required for hepcidin induction, explaining the fact that a defect in Tfr2 or HFE could result in decreased hepcidin synthesis (Gao et al, 2009).

V. CLINICAL FEATURES.

V.1 General Presentation.

The natural history of HH evolves through a series of stages. During their first 20 years of life, patients with HH may undergo clinically insignificant iron accumulation, with 0–5 g of parenchymal iron storage. In their 20s to 40s, patients may evolve to a stage of iron overload, but without symptomatic disease, with 10–20 g of parenchymal iron storage. Finally, by the age of 40, patients may progress to a stage of iron overload with parenchymal organ damage, with more than 20 g of iron storage in the liver, heart and endocrine tissue (Adams et al, 1997). In men, HFE HH rarely becomes symptomatic before the fourth or fifth decade of life except in juvenile HH. In women, menstruation, pregnancy and lactation delay iron accumulation by approximately 10 years and symptomatic HH usually presents after the menopause.

Due to increasingly early diagnosis, the classic triad of HH –diabetes, bronze pigmentation of the skin and cirrhosis-is now rare and not representative of the majority of HH patients at diagnosis. Early disease manifestations are often non-specific and the most frequently experienced symptoms are fatigue and joint pain (Brissot et al, 2011). However, symptoms are progressive and if not treated, patients may develop end-organ dysfunction (table 2) (McDonnell et al, 1999*;Brissot et al, 2011).

Table 2. Frequency of signs and symptoms in hereditary haemochromatosis

Sign or symptom	Frequency (%)
At diagnosis	
Fatigue	74
Arthralgia	56
Loss of libido	30
Skin bronzing	25
Current symptoms with phlebotomy treatment	
Fatigue	60
Joint pain	50
Skin hyperpigmentation	12
Diabetes mellitus	48
Loss of libido	23
Liver problems	10
Electrocardiographic abnormalities	12

Adapted from Brissot et al, Transfusion 2011

Most HH is now diagnosed when elevated serum ferritin levels are found on routine laboratory screening or when targeted screening is performed because of familial HH.

V.2 Arthropathy

Joint complaints are one of the most frequent symptoms of HH (De Seze et al, 1972; Pawlotsky et al, 1999; Brissot et al, 2011; Guggenbuhl et al, 2011; Carroll et al, 2012). They occur in 33–70% of patients and are often the first manifestation of disease. Affected patients may present with arthralgia or an arthropathy which usually resembles non-inflammatory osteoarthritis (OA) and calcium pyrophosphate dihydrate deposition (CPPD) disease. Presentation is therefore often non-specific and because of the practical consequences of early diagnosis (to prevent life threatening complications of the disease), rheumatologists should very much remain alerted by a younger age for classical osteoarthritis or CPPD disease. In a recent study, diagnosis was made only 9 years after the onset of joint complaints and the mean age of onset was 45.8 ± 13.2 years (Sahinbegovic et al, 2010*). Therefore, articular features appear frequently at a younger age than in OA or CPPD disease; their occurrence in a person below the age of 55–60 years should prompt strong suspicion of HH. Involvement of the second and third metacarpophalangeal (MCP) joints, with bony enlargement rather than swelling due to synovitis, is seen in one third of HH patients (Valenti et al, 2008) and is very suggestive of HH. Arthropathy in HH may also display the full spectrum of CPPD disease, with acute calcium pyrophosphate crystal arthritis ('pseudogout'), chondrocalcinosis and chronic arthropathy. Joint inflammation is typically minimal, but acute attacks of inflammation with bilateral destruction of the MCP joints may occur. Acute attacks of synovitis probably result from calcium pyrophosphate crystal deposition.

Reduced flexion at the MCP joints has been noted, but ulnar deviation, a common finding in rheumatoid arthritis (RA), has not been reported in HH. Radiographs differ from those in RA and typically exhibit joint space narrowing, fine subchondral bone sclerosis underlining bone contours, epiphyseal small cysts and frequent osteophytosis with no marginal erosion. This radiological picture is very suggestive of HH when it develops at the second and third MCP joints, associated with large hook-like osteophytes of the proximal radial side of MCP joints (figures 1 and 2). Chondrocalcinosis is seen in 10–30% of patients (figures 1 and 3) and the aetiological work-up of CPPD disease should include a search for HH. HH arthropathy is usually polyarticular and may involve many joints, in particular the knees and hips. HH should particularly be looked for when OA features are present in joints rarely affected by primary OA, including the wrist, the glenohumeral joint with no rotator cuff rupture, and the ankle. Non-traumatic OA of the ankle is clearly one of the presenting features of HH (Jacki et al, 1999; Schmid et al, 2003; Carroll, 2006; Carroll et al, 2012). Hip involvement does not differ from regular OA but is been found to be more frequent and more severe. The rate of total joint prosthesis (most frequently of the hip, followed by the knee) appears to be five- to nine fold higher than in the general population, particularly with HFE C282 homozygosity associated with an increased risk of both single and bilateral total hip replacement (Richette et al, 2010b; Sahinbegovic et al, 2010*; Wang et al, 2012) and prostheses are indicated at a younger age. HH has also been reported as a cause of aseptic necrosis of the femoral head (Rollot et al, 2005).

Arthropathy may significantly affect the quality of life in patients with HH, even more so than diabetes or cirrhosis .

Figure 1. Anteroposterior view of the hand of a patient with haemochromatosis with severe joint space narrowing, most marked at the metacarpophalangeal (MCP) joints. A small amount of chondrocalcinosis can be seen at the second MCP joint (arrow).

Figure 2. Metacarpophalangeal (MCP) joint involvement in hereditary haemochromatosis. Note the presence of joint space narrowing, fine subchondral bone sclerosis, containing small cysts, and large osteophytes. Erosion of the MCP joints can also be seen, a rare finding in hereditary haemochromatosis.

Figure 3 Anteroposterior view of the knee showing chondrocalcinosis

A direct role of iron in the arthropathy has never been clearly established even if many elements go in this direction. Pathological studies demonstrate the deposition of iron in the synovium and cartilage, which could play a pathogenic role (Schumacher, 1972). Free iron can generate free radicals able to induce lipid peroxidation and collagen cleavage, promoting immune complex formation, and can favour deposition of calcium pyrophosphate crystals by inhibition of the membrane-bound alkaline phosphatase. A correlation between the extent of iron deposition, as measured by ferritinaemia, and the presence or severity of the arthropathy has been observed by some authors, in particular when ferritinaemia exceeded 1000 µg/L (Pawlotsky et al, 1999; Valenti et al, 2008), but appears to be inconsistent across studies. Moreover, arthropathy generally does not respond to iron removal (McDonnell et al, 1999*; Sahinbegovic et al, 2010*), in contrast with the visceral localisations of HH, and can even arise during the initial phase of phlebotomy (Brissot et al, 2011). A recent study has even observed that phlebotomy was followed by an increase in the serum levels of CTXII, a marker of cartilage collagen degradation, and suggests that cartilage is sensitive to iron excess in patients with HH (Richette et al, 2010a).

V.3 Osteoporosis

Despite the decrease in hypogonadism, due to earlier diagnosis and treatment, osteoporosis, defined as a T score of <2.5 or lower, is still seen in roughly one third of patients with HH (Guggenbuhl et al, 2005; Valenti et al, 2009). The incidence of fractures is uncertain. Hypogonadism and liver cirrhosis have become rare. A Genetic hemochromatosis animal models have shown that excess iron has a direct impact on osteoblast function, with decreased bone formation, alterations in bone mass and microarchitecture, (de Vernejoul et al, 1984; Guggenbuhl et al, 2011; Doyard et al; PLoS One 2016) and on apatite crystal growth (Guggenbuhl et al, 2008)

V. 4 Hepatic Manifestations

Historically, more than 95% of symptomatic patients with HH had hepatomegaly, elevated liver enzymes or cirrhosis, owing to progressive iron deposition in the liver (Fracanzani et al, 1995; McDonnell et al, 1999*). Cirrhosis and cirrhosis-associated complications like oesophageal varices and variceal haemorrhage, account for approximately 89% of HH-related deaths (Niedermaier et al, 1996*). If treated with phlebotomy in the pre-cirrhotic stage, individuals with HH have now normal life expectancy (Bardou-Jacquet E et al, 2015). Iron overload in HH may potentiate the development of alcoholic liver disease and also hepatic fibrosis in patients with hepatitis C virus infection (Elmberg et al, 2003). One of the most serious complications of hepatic iron overload was the occurrence of hepatocellular carcinoma (HCC) (Thorburn et al, 2002). HCC accounted for approximately 30% of all deaths in HH (McDonnell et al, 1999*). The risk of HCC in patients with HH is increased approximately 20-fold (95% CI 16 to 22) compared with the general population (EASL European Association for the Study of the Liver, 2010*). The risk was highest in men, smokers and heavy alcohol users, and was not increased among first-degree relatives (Elmberg et al, 2003). Overall, patients with HH and cirrhosis have an estimated 5% annual risk for HCC. The risk for HCC continues to be a threat even after adequate phlebotomy. HCC is rare in non-cirrhotic HH.

Liver histology using the Perls stain is a way to document iron overload but its indication for diagnostic purposes has considerably decreased since the availability of the HFE genotyping test. It is still indicated in assessment of extensive bridging fibrosis and as a prognosis indicator, when liver cirrhosis is suspected, in particular in the case of hepatomegaly, high serum aspartate aminotransferase or elevation of ferritin above 1000 µg/L. Biological markers of hepatic fibrosis such as serum hyaluronic acid, and ultrasound elastography may become an alternative approach to liver biopsy for the diagnosis of advanced fibrosis (EASL, 2010*).

V.5 Diabetes Mellitus

Diabetes mellitus (DM), as a result of progressive iron deposition in the pancreas has become rare as it is effectively prevented by phlebotomy. Most patients with DM secondary to HH also have liver disease or skin hyperpigmentation (Salonen et al, 2000).

V.6 Cardiac Manifestations

In the past, approximately 15% of patients with HH presented with cardiac disease. Excess iron deposition within the myocardium may lead to a mixed dilated-restrictive or dilated cardiomyopathy, characterised by the development of heart failure and conduction disturbances, such as atrial fibrillation or the sick sinus syndrome. Electrocardiographic abnormalities include a decrease in QRS amplitude and T-wave flattening or inversion. Cardiac iron deposits produce a diagnostic pattern on cardiovascular MRI in which the myocardium has very low signal intensity. Treatment with phlebotomy has been associated with reversal of the left ventricular dysfunction, but in subjects with advanced disease, damage may be irreversible (Rivers et al, 1987).

V. 7 Hypogonadism

Hypogonadism with loss of libido has become rare. Repeated phlebotomy to remove excess tissue iron deposits may reverse the hypogonadism in men under the age of 40 years (McDermott and Walsh, 2005).

V.8 Hypothyroidism

Hypothyroidism in HH may be due to excess iron deposition in the thyroid gland, causing fibrosis and the development of antithyroid antibodies (Edwards et al, 1983). Affected individuals typically require lifelong supplementation therapy.

V.9 Dermatological Manifestations

Skin hyperpigmentation in HH reflects a combination of increased melanin and iron deposition around sweat glands (melanoderma) (McDonnel et al, 1999*). When severe, it has a grey or brownish colour, with slate-grey patches in the oral mucosa. Generalised hyperpigmentation usually occurs but can be limited to the face, neck, extensor aspects of the lower forearms, dorsum of the hands, lower legs, genital region and scars. Skin atrophy, flattening of the nails and loss of body hair are also common

V.10 Susceptibility to Infections

Susceptibility to specific infections has been described in patients with HH. Iron overload of macrophages can diminish phagocytosis of *Listeria*, while high serum iron levels may increase bacterial virulence (van Asbeck et al, 1982). *Yersinia enterocolitica* and *Vibrio vulnificus* are both siderophoric (iron-loving) and may pose an increased risk of infection in patients with HH (Carniel et al, 1987). *V. vulnificus* occurs in uncooked seafood (Bullen et al, 1991).

VI. Diagnosis

When the disorder is suspected, the first step towards diagnosis is to demonstrate iron overload. HH is then further diagnosed by genotyping the HFE gene. The main difficulty is to suspect the disorder when facing early, frequently non-specific symptoms, for example fatigue or arthralgia. Screening of first-degree relatives of HH patients is very important for early diagnosis (see in-depth discussion). As serological testing for iron markers has become widely available, the majority of patients with HH are now identified while still asymptomatic and without evidence of hepatic fibrosis or cirrhosis.

VI. 1 Serological Markers of Iron Overload.

Most of HH are characterized by increase of the transferrin saturation and increase of ferritin.

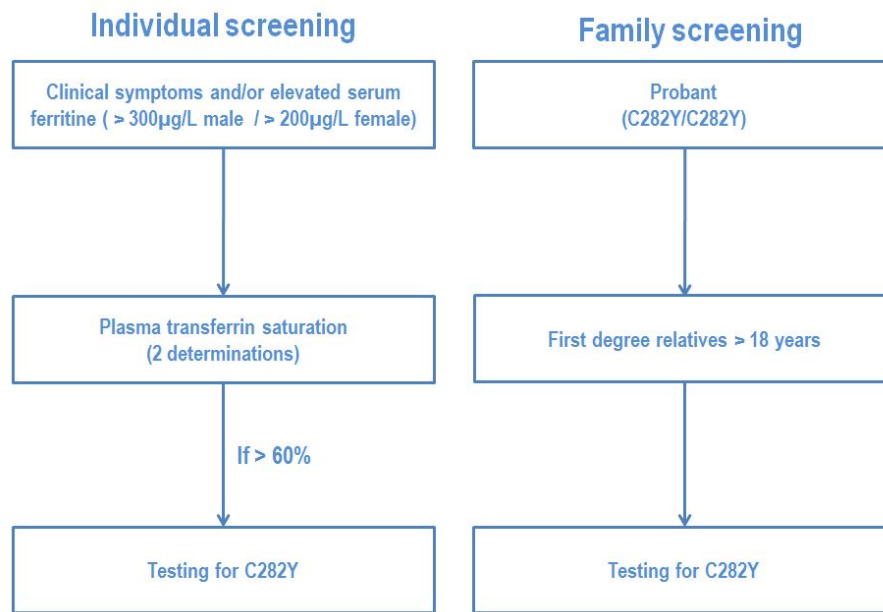

Transferrin saturation, obtained by dividing the serum iron by the total iron binding capacity, is the proportion of the iron transport protein transferrin that is saturated with iron. Overnight fasting avoids circadian and postprandial variations and eliminates 80% of false-positive transferrin saturation results. In HH, transferrin saturation is generally increased during the day as a result of innately low hepcidin. Expert consensus considers 45% to be the upper limit of normal in the non-fasting situation, in the absence of inflammation. For many years, transferrin saturation was endorsed as an ideal test for the diagnosis of haemochromatosis, because most C282Y homozygotes with iron overload have high transferrin saturation (>45% in women and >50% in men). The unsaturated iron-binding capacity is a one-step test that costs less than the transferrin saturation test and has similar sensitivity and specificity. However, much biological variation exists within individuals for both tests, including large numbers of false positives and the inability to detect some C282Y homozygotes with a high ferritin level.

Serum ferritin estimates the total body iron stores. A ferritin value greater than 300 µg/L in men and greater than 200 µg/L in women provides additional support for iron overload. Serum ferritin levels may be influenced by inflammatory conditions, chronic hepatitis C, alcohol-induced liver disease and neoplastic diseases. However, serum ferritin combined with transferrin saturation has a negative predictive value of 97%. In confirmed HH, serum ferritin levels >1000 ng/mL may accurately predict the degree of hepatic fibrosis (cirrhosis). A fasting transferrin saturation of less than 45% with a normal serum ferritin requires no further evaluation.

Ferritin but not transferrin saturation can be increased in diseases other than HFE haemochromatosis, including inflammation, chronic alcohol consumption, liver cell necrosis, metabolic syndrome, non-alcoholic steatohepatitis, Gaucher disease, refractory haemolytic anaemia. These conditions should be excluded before HFE genetic testing (EASL, 2010*; van Boven et al, 2011*).

VI.2 Genotype Testing

Patients with elevated transferrin saturation and serum ferritin levels, not explained by other disease, require further genotypic testing. The presence of the HFE mutations C282Y and H63D can be detected by polymerase chain reaction using whole blood samples (Feder et al, 1996*). Individuals with serum indicators of iron overload who are homozygous for the C282Y mutation require phlebotomy therapy and screening of first-degree relatives for HH. According to recent guidelines, C282Y/H63D compound heterozygotes and H63D homozygotes should be further investigated for other causes of hyperferritinaemia because of the relative rarity of HH in these patients (EASL, 2010*).

Table 3. Flowchart genetic screening haemochromatosis.

Adapted from Brissot and Loréal, J Hepatology 2016; Powell et al, Lancet 2016

VI.3 Other Diagnosis Tests

Since the availability of the HFE genotyping test, liver biopsy, which allows demonstration of iron overload of the liver, for the diagnosis of HH has become very rare. Non-invasive MRI quantification of iron liver load is used in clinical practice. Liver biopsy is restricted to patients with no clear explanation for the iron overload and those with high risk of cirrhosis (hepatomegaly, transaminases increase or ferritin > 1000). Quantitative phlebotomy may be also used to quantify iron overload by determining the number of phlebotomies required to induce iron deficiency (EASL, 2010*).

VII. Treatment

The current standard of care is phlebotomy that is considered effective with benefits in terms of morbidity and long-term survival (Niedermaier et al, 1996*; McDonnell et al, 1999*). It prevents the occurrence of life threatening complications such as diabetes, cirrhosis and hepatocellular carcinoma, heart failure. Phlebotomy lessens some clinical manifestations and organ damage (malaise, fatigue, abdominal pain, skin pigmentation). Diabetic patients may require less insulin. Regression of hepatic fibrosis can be observed in some patients, the best results occurring when fibrosis is mild (European Association for the Study of the Liver, 2010*). Iron-related joint disease and other manifestations as cardiac conduction abnormalities do not consistently respond to phlebotomy (Bardou-Jacquet et al; 2017). Therefore, early identification and treatment of those at risk is required. A European consensus-based recommendation (EASL, 2010*) is to start phlebotomy when serum ferritin levels rise above local reference values (usually 300 µg/L in men and 200 µg/L in women). However, as

not all patients with raised serum ferritin show further increases, a watchful approach for asymptomatic patients with a moderate increase in serum ferritin levels, with phlebotomy only when ferritinaemia increases progressively, might be an alternative. No special dietary restrictions are recommended

VII.1 Phlebotomy

Phlebotomy is used to reduce levels of excess iron by removing red blood cells and to maintain this state of iron balance over a patient's lifetime. In the induction-phase, the aim of bloodletting is to decrease serum ferritin levels to 50 µg/L or less. Weekly removal of one unit (without exceeding 7 ml/kg) of blood, which contains approximately 200–250 mg of iron, usually allows the target SF level to be reached within 1–2 years. In the maintenance-phase, the frequency of maintenance phlebotomies varies among individuals. On average, three to four phlebotomies per year for men, and one to two phlebotomies per year for women should keep the SF levels at 50 µg/L or less. Each venesection should be preceded by measurement of the haematocrit. The haematocrit should have returned to within 10 points of, or be no lower than 20% below, its starting value. Transferrin saturation may remain elevated until iron stores are depleted and worse outcomes are associated with persistent increases in transferrin saturation during maintenance therapy (Bardou-Jacquet et al; 2017). Adequate hydration before and after treatment and avoidance of vigorous physical activity for 24 h after phlebotomy are recommended (EASL, 2010*). SF levels of less than 25 ng/mL indicate iron deficiency and require temporary cessation of phlebotomy. Iron deficiency anaemia should be avoided. Side effects as tiredness are frequently reported. Rapid mobilisation of iron may increase the risk of cardiac dysrhythmias and cardiomyopathy. Iron supplements and supplemental vitamin C should be avoided by patients undergoing phlebotomy, as vitamin C may accelerate the mobilisation of iron. (Brissot et al, 2011).

VII.2 Alternatives Therapies

Chelation therapy is restricted to a minority of patients with contraindications for venesection including severe anaemia, cardiac failure, poor tolerance or problems with venous access. A daily 2 g subcutaneous dose of deferoxamine infused over 8 h has been shown to be effective (Barton, 2007). An oral iron chelator has also been developed and is starting to be tested in HH. In the future, promising potential therapies include mini hepcidin and BMP6 agonists.

VII.3 Liver Transplantation

End-stage liver disease in HH can be treated with liver transplantation but survival is reduced compared with transplantation in patients without HH, especially when HCC is present. Survival at 1, 3 and 5 years after

transplantation was 72%, 62% and 55%, respectively. Death was secondary to perioperative cardiac or infection-related complications (Crawford et al, 2004).

VIII. Prognosis

The degree of iron overload has a direct impact on the life expectancy of an individual with HH. Major causes of death are decompensated cirrhosis, HCC, DM and cardiomyopathy (Niederau et al, 1996*). These occur at frequencies which are 10–120-fold higher than in an age-matched and sex-matched population without HH. Cardiac dysrhythmias and cardiomyopathies are the most common causes of sudden death in patients with HH. Survival in HH patients in whom treatment is initiated before the development of cirrhosis or diabetes, is similar to that in the general population. Reversibility of changes following adequate iron removal is more likely early in the course of the disease, but can occur even in patients with cirrhosis and varices.

SUMMARY POINTS

- Hereditary haemochromatosis (HH) is the most common identified genetic disease in the white population. In Caucasians, it is most often due to homozygous C282Y HFE gene mutation (> 90 %) with an increased intestinal iron absorption; other genetic mutations more rare have been described.
- The clinical manifestations of HH are related to excessive iron accumulation in tissues, especially the liver, heart, joints and endocrine organs, usually manifesting in adults in their 40s and 50s.
- Phenotypic HH may arise when both alleles of chromosome 6 possess the C282Y mutation (homozygous state) or with the C282Y mutation on one chromosome and H63D on the other (compound heterozygous state).
- Early disease manifestations are non-specific and may include fatigue, arthralgias, weight loss, abdominal pain and loss of libido.
- Patient's quality of life is often altered by the rheumatological complications of HH, particularly joint symptoms and sometimes osteoporosis. Arthropathy is frequently an early feature of HH and it is important it is recognised to allow early treatment and improved prognosis. It may resemble non-inflammatory osteoarthritis involving the second and third metacarpophalangeal and other joints. HH is a cause of calcium pyrophosphate dihydrate deposition (CPPD) disease. Arthropathy in HH is severe, impairs the quality of life and is frequently the indication for total hip arthroplasty.
- Cirrhosis and cirrhosis-associated complications such as oesophageal varices and variceal haemorrhage account for approximately 89% of HH-related deaths. Early treatment can avoid this serious outcome.
- The risk of hepatocellular carcinoma (HCC) in patients with HH is increased approximately 20-fold.
- Diabetes mellitus caused by progressive iron deposition in the pancreas is a feature of HH which can be prevented by early treatment.
- Cardiac dysrhythmias and cardiomyopathies are the most common cause of sudden death in iron overload states.
- Initial screening of individuals with suspected iron overload and those over the age of 20 years who are first-degree relatives of known cases of HH should be done by measurement of transferrin saturation after an overnight fast. Simultaneous serum ferritin determination increases the predictive accuracy for the diagnosis of iron overload.
- Genotyping to detect HFE mutations should be performed for individuals who have abnormal iron studies and for first-degree relatives of identified HH homozygotes.
- Liver biopsy is now rarely indicated for the purpose of diagnosis. Initiation of phlebotomy therapy before cirrhosis or diabetes develops significantly reduce the morbidity and mortality of HH.
- If tolerated, therapeutic phlebotomy should be continued until serum ferritin falls below 50 µg/L. Maintenance phlebotomies should keep the serum ferritin concentration at 50 µg/L or less, and should be continued for life.

Part II: Gaucher's disease

LEARNING OBJECTIVES

- Outline the pathophysiology of Gaucher's disease
- Describe the different clinical types of Gaucher's disease
- Describe the skeletal involvement in Gaucher's disease
- Describe the radiological findings in Gaucher's disease
- Describe treatment options in Gaucher's disease

I INTRODUCTION

Gaucher's disease GD is a rare inborn error of metabolism with few rheumatological manifestations. (Grabowski et al, 2015*). As the risk of skeletal disease with irreversible complications is reduced with early initiation of enzyme replacement therapy, rheumatologists should be alert to splenomegaly or hepatomegaly of unknown cause in the presence of bone disease and/or unexplained pain and should include GD in the differential diagnosis.

II PATHOPHYSIOLOGY

GD was first described by Philippe CE Gaucher in 1882 as 'epithelioma of the spleen', in a patient with massive hepatosplenomegaly and haematological features suggestive of leukaemia. GD is a lysosomal glycolipid storage disease due to mutations of both alleles of the acid β -glucosidase gene on chromosome 1 (long arm at position 22 1q22) leading to decreased activity of the lysosomal enzyme, acid β -glucosidase in cells (especially macrophages) of the reticuloendothelial system. Glucocerebrosidase normally catabolises glucocerebroside derived from the degradation of membranes, into ceramide and glucose. Glucocerebroside accumulation within the lysosomes of macrophages ('Gaucher cells') (figure 1) in the spleen, liver, bone marrow and bone leads to organomegaly, bone disease, cytopenia and chronic macrophage activation with inflammasome activation (Grabowski et al, 2015*; Mucci et al, 2015; Migdalska-Richards et al 2016). An animal model with conditional GBA1 deletion in mice shows a defect in osteoblast differentiation and function with an increase of bone resorption (Mistry et al, 2010*). Bone marrow fibrosis may cause localised loss of haematopoiesis, while thrombocytopenia results from decreased platelet production and splenic sequestration.

Figure 1. Light microscopy aspect of a Gaucher cell with characteristic 'wrinkled tissue paper' appearance of the cytoplasm

GD is the most common inherited glycolipid storage disease, with a worldwide incidence of approximately 1 in 57 000 births, and about 10 000 patients world-wide. More than 400 discrete mutant alleles have been identified in the β -glucocerebrosidase gene (GBA1). Three different clinical types can be distinguished. Type 1 (GD1), the adult non-neuropathic form, is the most frequent type and occurs predominantly in populations of European Ancestry and Ashkenazi Jews. More than 95% of GD patients have GD1. Type 2 Gaucher's disease, the infantile

acute neuropathic form and type 3, the juvenile subacute neuropathic form, are much less common and occur predominantly in non-Jewish patients (Grabowski et al, 2015*) .

III. CLINICAL FEATURES

GD is characterized by complex multiorgan involvement with non-specific symptoms. The most commonly reported signs and symptoms at diagnosis are splenomegaly, hepatomegaly followed by bone manifestations. We will focus on GD1.

Table 1. Key features of the three types of Gaucher disease.

Key features	Type 1 « non neuronopathic »	Type 2 «acute neuronopathic»	Type 3 «subacute neuronopathic»
Incidence	1:40000–1:60000 1:850 in Ashkenazi Jews	<1:100000	<1:50000 to <1:100000
Transmission	Autosomal recessive	Autosomal recessive	Autosomal recessive
Ethnic predilection	Pan ethnic/Ashkenazi Jews	Pan ethnic	Pan ethnic/Norrbottnian Sweden
Peak age at onset	Any age (birth to old age)	Infancy	Childhood/adolescence
Hepatosplenomegaly	+ → +++	+ → ++	+ → ++++
Haematological symptoms	+ → +++	+++	+ → +++
Skeletal involvement	+ → +++	Absent	++ → ++++
Neurodegeneration	Absent	+++	+ → +++ (progressive)
Age at death	Childhood/adulthood	Median 9 months	Childhood/adulthood

GD1 is heterogeneous in age at presentation, clinical expression, disease severity and progression. Two-thirds of patients are diagnosed by 20 years of age. However, some may present as infants, while others remain asymptomatic throughout life. The principal presenting feature is painless splenomegaly. Hypersplenism with thrombocytopenia, anaemia and leukopenia occurs frequently, but splenic infarction or rupture is rare. Hepatomegaly usually occurs later in the course of the disease. Hepatic fibrosis is common, but liver failure and portal hypertension are rare. Patients often also present with lymphadenopathy.

Skeletal involvement affects more than 80% of patients, often with high morbidity and a major impact on quality of life. Before any treatment, 63% of patients complain of bone pain in the back, hips, legs, and shoulders. Fractures occur most frequently in the vertebral spine spontaneously or with minimal trauma (36.4% of all fractures), followed by the lower extremities (Javier et al 2011; Grabowski et al, 2015*). Neurologic compression and thoracic hyperkyphosis have been reported as being consequences of severe or multiple vertebral fractures.

Failure of bone modelling during growth is the most characteristic skeletal abnormality, present in about 80% of GD1 adults. The so-called Erlenmeyer flask deformity (expansion of the contours of long tubular bones with loss of the normal concavity of the bony outline) is very suggestive of GD1, though not pathognomonic. Osteonecrosis and bony infarctions are the most common bone complications in GD1 and the most frequent cause of chronic pain and limitation of function (Khan et al, 2012*). Both are the consequences of sudden ischemia in an infiltrated bone area and result in acute-onset episodes (bone crisis). All bones may be involved, including flat bones. Symptoms include acute pain, tenderness, and fever, similar to the symptoms of osteomyelitis or septic arthritis. Epiphyseal osteonecrosis frequently occurs at multiple sites and affects the femoral heads, humeral heads. Symptomatic bone involvement becomes less common after splenectomy. Bone marrow encroachment and fibrosis may result in localised loss of haematopoiesis. However, the degree of anaemia and thrombocytopenia is more often related to splenic sequestration and depends on whether or not the patient has had splenectomy.

Other infrequent manifestations include interstitial lung disease due to infiltration of Gaucher cells into the interstitial and alveolar spaces, and pulmonary hypertension due to infiltration and occlusion of pulmonary capillaries. Patients with Gaucher's disease appear to have an increased risk of haematological malignancies and multiple myeloma. Gaucher's disease has also been associated with Parkinsonism (Grabowski et al, 2015*; Migdalska-Richards et al, 2016).

Pregnancy in GD1 usually has a good outcome. The most common serious complication is postpartum bleeding. Children with GD1 may have growth retardation and delayed onset of puberty.

The clinical course of GD1 is usually progressive but varies from rapid progression in severely affected children to a more insidious course in asymptomatic adults. Morbidity and mortality in symptomatic patients results from the sequelae of severe bone disease, bleeding complications, infections, liver failure or severe pulmonary disease (Weinreb et al, 2013*).

IV. DIAGNOSIS

IV.1 Laboratory and Radiological Findings

Typical laboratory findings are thrombocytopenia and anaemia, especially in patients with splenomegaly. Liver enzymes may be mildly elevated in patients with hepatomegaly. Biochemical markers reflecting overloading of activated macrophages, such as plasma tartrate-resistant acid phosphatase, angiotensin-converting enzyme, ferritin, chitotriosidase, and recently glucosylsphingosine are useful for evaluating disease activity and monitoring response to therapy (van Dussen et al, 2011; Rolfs et al, 2013).

Radiologic bone manifestations are found in more than 95% of patients with features and frequency depending on the imaging method used. Radiographs may show increased symmetrical radiolucency and cortical scalloping

with thinning of the axial skeleton and proximal long bones, prominent in the distal portion of the femur and tibia.

Plain X-rays may also show fractures and lytic lesions. The vertebral bodies may show identical deformities as seen in sickle cell anaemia, with step-like depressions of the superior and inferior margins, called 'H vertebra'. The extent and severity of the disease vary and are poorly evaluated by radiography, computed tomography (CT), or bone scintigraphy. Magnetic resonance imaging (MRI) has been shown to be the most sensitive technique for detecting early bone marrow changes and for assessing the extent and severity of marrow involvement. Computed tomography, MRI or abdominal sonography of the liver and spleen may demonstrate hepatosplenomegaly and can be used to assess response to therapy (Grabowski et al, 2015*). A decrease in bone mineral density by Dual-energy X-ray absorptiometry is reported (osteopenia in 42% of cases) and is correlated with the severity of skeletal involvement.

Figure 2. Typical features of ischemic bone complications in GD: radiograph of the left femoral diaphysis of a 52-year-old man showing osteopenia, osteolytic lesions, cortical thinning, and scalloping

IV.2 Diagnosing Gaucher's Disease

The most appropriate and less invasive diagnostic test for detecting GD1 is demonstrating decreased or absent acid β -glucosidase activity in leucocytes and/or by molecular analysis of the GBA1 gene instead of the bone marrow biopsy often made for patients being evaluated for splenomegaly, anaemia and/or thrombocytopenia. Mutation analysis may further help to predict clinical findings and to identify affected but undiagnosed family

members or heterozygote carriers (Grabowski et al, 2015*). Recently, an easy screening evaluation of GBA activity in dried blood spots has become available.

V TREATMENT

Treatment goals in Gaucher's disease are increasing survival, prevention of irreversible damage, elimination of symptoms, and improvement of overall health and quality of life (Weinreb et al, 2013*; Zimran et al, 2015*; Zimran et al, 2016*). Therapeutic goals for skeletal involvement are to lessen or eliminate bone pain within 1 to 2 years, prevent bone crises, prevent osteonecrosis and subchondral joint collapse and improve BMD (Pastores et al, 2004*).

V.1 Enzyme Replacement Therapy ERT

Venous infusions of ERT are used for more than two decades (Weinreb et al, 2013*). Three forms of macrophage-targeted glucocerebrosidase are now available: recombinant glucocerebrosidase produced by DNA technology (imiglucerase, Cerezyme), human glucocerebrosidase produced in a human cell line with gene activation technology (velaglucerase alfa, VPRIV), and a carrot cell-expressed human recombinant β -glucocerebrosidase (taliglucerase alfa, Elelyso) (Weinreb et al, 2013*; Zimran et al, 2015*; Zimran et al, 2016*).

ERT usually results in improvements in all clinical and laboratory parameters of GD1. Currently recommended therapeutic regimens start with 2-hour intravenous infusions of 60 IU/kg every 2 weeks. Glucocerebrosidase infusions have a good control over haematological and visceral parameters (hepatosplenomegaly) within 12 to 20 weeks, although a bone response requires a longer period with an increase in BMD and a significant positive impact on quality of life (Sims et al ;2008). MRI scores and recently whole-body magnetic resonance imaging MRI have been proposed for evaluating the therapeutic bone response.

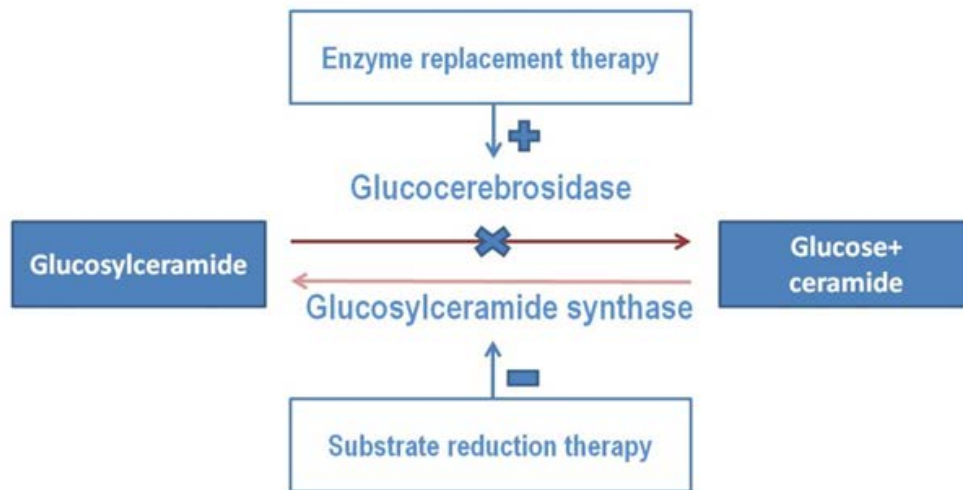

ERT may be less effective in patients with neuropathic GD. The recombinant enzyme does not cross the blood–brain barrier and is therefore likely to have only a limited impact on neurological involvement.

V.2 Substrate Reduction Therapy

Substrate reduction therapy (Figure 3) is an alternative treatment in patients with GD1. Miglustat (Zavesca) is an oral iminosugar that decreases substrate synthesis (Pastores et al; 2007). It is approved for patients with mild to moderate GD1 who are intolerant of imiglucerase or unwilling to take ERT. Eliglustat (Cerdelga) is an oral ceramide analogue that inhibits glucosylceramide synthase, the enzyme responsible for biosynthesis of glucosylceramide which accumulate in GD, thus reducing glucosylceramide accumulation (Belmatoug et al; 2017). Eliglustat is approved as a first line treatment for adults (> 18 years) with GD1 who are CYP2D6 extensive,

intermediate or poor metabolizers. Miglustat does cross the blood–brain barrier and may therefore have potential benefit in neuropathic GD (Pastores et al, 2007*).

Figure 3: Mechanisms of action of treatment in Gaucher disease

V.3 Symptomatic Treatments

Antiresorptive therapy with high-dose alendronate in addition to ERT increases BMD at 24 months without radiologic modification of focal lesions (Wenstrup et al; 2004). The effect on the risk for fractures is unknown. As vitamin D deficiency seems to be frequent in patients with GD1, optimization of vitamin D levels is recommended. Osteonecrosis often require surgery earlier than in the general population but improved surgical techniques have increased the probability of good results and decreased the postoperative complications that were reported in historical series (Khan et al; 2012).

**SUMMARY POINTS**

- Gaucher's disease GD is a rare autosomal recessive lysosomal glycolipid storage disease in which gene mutations on chromosome 1q22 lead to decreased activity of the enzyme glucocerebrosidase in cells (especially macrophages) of the reticuloendothelial system.
- Clinical manifestations develop as glucocerebroside and other glycolipids accumulate within the lysosomes of macrophages ('Gaucher cells') in the spleen, liver, bone marrow and bone.
- Type 1 GD, the adult non-neuropathic form, is the most common clinical type. Type 2, the infantile acute neuropathic form and type 3, the juvenile subacute neuropathic form, are much less common.
- The principal presenting feature in GD1 is often painless splenomegaly, with thrombocytopenia, anaemia and leucopenia.
- Skeletal disease affects more than 80% of GD1 patients with a major impact on quality of life. Osteopenia and osteolytic lesions can cause pathological fractures of the long bones, vertebral compression. Osteonecrosis and bony infarctions are the most common bone complications, the most frequent cause of chronic pain and limitation of function.
- MRI is the most sensitive technique for detecting early bone marrow changes and for assessing the extent and severity of marrow involvement. The most appropriate and least invasive diagnostic test for detecting GD1 is demonstrating decreased or absent acid β -glucosidase activity in leucocytes and/or by molecular analysis of the GBA1 gene
- GD1 must be treated early with enzyme replacement therapy or substrate reduction therapy to prevent irreversible severe bone complications. Bone disease remains a major therapeutic issue in GD1.

Part III: Histiocytosis

LEARNING OBJECTIVES

- Outline the pathophysiology of Langerhans cell histiocytosis (LCH) and importance of the BRAF mutation
- Describe the most frequent localisation of LCH
- Describe some clinical features of LCH, especially bone and joint involvement
- Describe the clinical workup of suspected LCH
- Describe some treatment strategies in LCH
- Describe the differences in clinical presentation between childhood LCH and adult LCH

I INTRODUCTION

There is some confusion over the terminology of histiocytosis. Despite proposals clarifying classification and terminology, different terminologies and interpretations are still used in the literature. In this review we will focus on bone and joint manifestations of Langerhans Cell histiocytosis (LCH). We will not discuss other forms of Histiocytosis such as Erdheim Chester Disease, Rosai Dorfman Disease or Juvenile Xanthogranuloma.

II PATHOPHYSIOLOGY

Histiocytosis is the name given to abnormal proliferation of histiocytes. The Langerhans cell derives from bone marrow dendritic cells and is capable of migrating to the skin, spleen and lymph nodes. It is an antigen-presenting cell and is positive for CD1a and CD207. On electron microscopy, pentalaminar Birbeck granules are easily recognised. In LCH, the abnormal cells are immature, poorly antigen presenting, and proliferating at a moderate rate. The disease is defined through a clonal (but not malignant) proliferation of Langerhans cells in various abnormal locations. Histologic findings may show various involvements of other cells such as macrophages, eosinophiles, or multinucleated giant cells. It has been unclear for many years whether immunologic or infection events are responsible for the disease. The main recent finding is the involvement of the oncogene BRAF : the mutation V600E has been found in 86.8% of multisystem forms with risk organ involvement, 68.6% of multisystem forms without risk organ involvement and 43.9% of single system patients (Héritier et al, 2016*; Badalian-Very et al, 2010).

III EPIDEMIOLOGY

LCH is a rare condition, and mostly (80% of cases) affects children. Yearly incidence rates are estimated at approximately 4.6 to 8.9 per million children, under 15 years (Guyot-Goubin et al, 2008; Stalemark et al, 2008, Ribeiro et al, 2015). The incidence of adult LCH is estimated to be less than 1 per million. It appears that LCH can present at any age during adulthood, and has usually a single system presentation (68% single system presentation versus 31% multisystem presentation). Located forms are observed more frequently in males, while generalised forms are found equally in males and females. Paediatric histiocytosis has a more severe phenotype (Minkov et al, 2005).

IV CLINICAL MANIFESTATIONS

The clinical manifestations are very diverse, and LCH has been described in almost every organ (Haupt et al, 2013*). Systemic signs such as fever and weight loss may also be presenting features, but are usually lacking. A considerable delay between the first onset of symptoms and the final diagnosis is common.

IV-1 Classical Presentation

IV-1-1 Skeletal disease

The classic single presentation is bone disease with osteolytic lesions without periosteal reaction, single or multiple, located in the skull, vertebra, jaw, ribs, flat bones (pelvis , scapula), and proximal portions of the long bones (figures 1 and 2). Classically hands and feet are spared. Localised pain may be present along with discrete local swelling but asymptomatic lesions are possible. Other clinical manifestations may be pathological fractures or osteoarthritis of the adjacent bones. In children, growth retardation can be a revealing symptom.

Figures 1 and 2. Osteolytic lesions in the skull, the pelvis and femoral neck of a 3-year-old child with Langerhans cell histiocytosis

IV-1-2 Skin and mucosa

Skin involvement is often mistaken for seborrheic dermatitis, but various forms of red papular rash have been described, with polymorphic presentation. Face, neck torso and groin are the main sites. It may include hypopigmented macules and eczema. Dermatological manifestation is often the first sign of underlying disease.

IV-1-3 Pituitary gland

Pituitary involvement causes diabetes insipidus through posterior pituitary involvement. Anterior pituitary deficit can be associated. When cranio-facial bones are affected, the risk of pituitary involvement increases.

IV-2 Other Manifestations

Many other clinical manifestations can occur, such as cytopenias due to bone marrow involvement, lungs manifestations with reticulo-nodular lung disease or lung cysts, or Lymphadenopathy. Other organs involved are the thymus, thyroid, spleen, liver, gastro-intestinal tract (sclerosing cholangitis) or the central nervous system

(CNS) with neurodegenerative syndromes. Systemic signs such as fever and weight loss have also been described.

IV-3 Clinical Classification (Girschikofsky and al, 2013*)

IV-3-1 Single system disease (SS-LCH)

When only one organ is involved, for example, when exclusive manifestations occur in the bone compartment. However, a single system LCH can have multifocal lesions within the bone.

IV-3-2 Multi system disease (MS-LCH)

When two or more organs/systems are involved. The classical presentation is the triad with bone, pituitary and skin lesions.

IV-3-3 Risk lesions

Risk lesions occur when risk organs/systems are involved, they are associated with poor prognosis (Haupt et al, 2013*, Girschikofsky et al, 2013*), including the spleen, the liver, the hematopoietic system (bone marrow) and central nervous system. Some “special” sites have to be considered as risk lesions because of high risk of functional impairment caused by neurological compression, including vertebral lesions, craniofacial bone lesions (mastoid, sphenoid, temporal bone) or orbital lesions.

IV-4 Differential Diagnosis

In these patients, it is important for the rheumatologist to consider the differential diagnosis of the most frequent osteolytic lesions, especially when lesions are unifocal. Malignancies include metastasis, osteoblastoma, chondroblastoma, or myeloma. Benign lesions include fibrous dysplasia, enchondroma, giant cell tumour, non-ossifying fibroma, bone cyst, hyperparathyroidism, or infection. Biopsy is the only certain procedure to rule out these differentials.

V DIAGNOSIS

V-1 Biopsy

The definitive diagnosis of LCH requires histological confirmation (Haupt et al, 2013*). Biopsy of the most accessible lesion should be performed whenever Histiocytosis is suspected on clinical, biological and/or radiological findings. Biopsy fragments should include immunophenotypic markings for CD1a and CD207, also

known as langerin (Girschikofsky et al, 2013*). Electron microscopy, for Birbeck granules identification, is no longer necessary for diagnosis (Haupt et al, 2013*).

V-2 Disease Severity Assessment

V-2-1 Skeletal involvement

Diagnosis and follow up include skeletal radiography and skeletal scintigram (bone scan).

V-2-2 Risk lesions assessment

Laboratory tests of the blood should include a complete blood count as well as screening for haematopoietic, liver, spleen and renal function. The clinical workup of suspected cases of LCH should include a chest X-ray and a survey of the skeleton; technetium bone scintigraphy is useful as a screening tool and can be completed with X-rays and computerised tomography. In cases with suspected CNS involvement, gadolinium-enhanced MRI scans are warranted. The usefulness of FDG-PET scan has still to be determined, but seems promising for follow up and for monitoring disease activity (Phillips et al, 2009).

V-3 BRAF Mutation

If LCH is confirmed, based on histological findings, screening for the BRAF gain of function mutation V600E should be discussed in specialized centres (through immunohistochemistry or molecular diagnostic methods), especially with young patients who have a multi system, severe or recurrent form, and resistant to treatment.

VI TREATMENT

Specific treatment depends on clinical presentation (SS-LCH or MS-LCH), or involvement of risk organs.

Although LCH is a rare condition, some studies have thoroughly investigated potential treatments. For obvious reasons formal treatment studies are not frequent in LCH, especially in adult forms . However, recent progress has been made and specific treatments emerge (table 1).

VI-1 SS-LCH with single bone compartment involvement.

No specific treatment is mandatory, but follow-up is necessary. Systematic radical curettage is not recommended. Spontaneous regression is possible. Bone curettage is generally sufficient when performed. Sometime the bone lesions heal after the biopsy or after corticosteroid injections. Preventive orthopaedic surgery is sometimes proposed because of fracture risk.

Systemic chemotherapy (corticosteroid/vinblastine) is only proposed when there is are severe multifocal bone lesions or “risk lesions” such as cranio-facial bone lesions or vertebral lesions with fracture risk.

Bone resorption inhibitors such as bisphosphonates (Morimoto et al, 2011) or denosumab (Makras et al 2017*) have shown interesting results, mostly on pain and should be considered when the bone disease is severe or associated with fracture/fracture risk. The effect on extra skeletal symptoms is not well known.

VI-2 SS-LCH concerning other single systems, without risk organ involvement

Studies indicate that in cases without risk organ involvement, prognosis (survival) is favourable, independent of the treatment strategy. Treatment is specific for the type of organ/system involved.

VI-3 MS-LCH or SS-LCH with risk organ involvement

Treatment should be initiated in specialized centres. Treatment is systemic and consists of chemotherapy. First line of treatment includes vinblastine and corticosteroid in paediatric cases. Children undergo 6 weeks to a year of treatment (Haupt et al 2013*, Gadner et al, 2011*). Treatments are summarized in Table 1.

The recent discovery of the BRAF mutation, as in Erdheim Chester disease, offers new promising therapeutic options: targeting the RAS pathway with BRAF inhibitors such as vemurafenib showing some efficacy in preliminary studies (Haroche et al, 2013; Charles et al, 2014).

Table 1. Summary of the treatments according to clinical presentation.

<i>Disease presentation</i>	<i>Treatment</i>
<ul style="list-style-type: none"> SS-LCH with bone impairment 	<ul style="list-style-type: none"> - Abstention to treat if unifocal / asymptomatic lesion. - Bone curettage and/or orthopaedic surgery if the lesion is at risk or symptomatic. - Corticosteroid injection if lesion is symptomatic. - Systemic chemotherapy is recommended only if there is a severe multifocal bone involvement, or risk lesions for nervous system. - Focal radiotherapy if lesions are difficult of access for other therapeutic options.
<ul style="list-style-type: none"> Other SS-LCH presentations without risk organ involvement 	<ul style="list-style-type: none"> - Symptomatic and specific of the organ affected.
<ul style="list-style-type: none"> SS-LCH with risk organ involvement MS-LCH 	<ul style="list-style-type: none"> - First line chemotherapy: vinblastine + corticosteroid (Haupt et al 2013*, Gadner et al, 2011*). - Second line chemotherapy: cladribine, cytarabine, hematopoietic stem cell Transplantation (Steiner et al, 2005). In adults: etoposide. - Radiotherapy (Kriz et al, 2013) has shown some efficacy but should be avoided in children, because of long-term adverse effects.

Adapted from Steiner et al, 2005;Gadner et al, 2011; Haupt et al 2013; ;Kriz et al, 2013 ;Morimoto et al, Cancer 2006;107:613**

VI PROGNOSIS

Prognosis is highly variable and depends on the age at onset, and the number and degree of dysfunction of affected organs. Five year relative survival is estimated at 90%, 79% survival under 1 year but 97% survival between 1 and 4 years of age, and 100% after 5 years. Patients with LCH with a low risk profile often achieve remission without long term sequelae. Patients with risk organ involvement are at considerable risk for long term complications. In 20% of cases, growth and development are impaired. In over 10% of cases, neurological problems can be expected due to vertebral compression. Moreover, in 20% of cases, symptomatic lesions of long bones are to be expected. Histiocytosis can be definitively cured due to natural evolution of the disease or secondary to treatment. However reactivations are possible in 25% to 45% of MS-LCH (Morimoto et al, 2006*; Cantu et al, 2012*). When multiple organs are involved, there is a lack of response to treatment, and a higher mortality. Finally, malignancy is found more frequently in patients surviving LCH, specifically acute myeloid leukaemia, lymphoblastic lymphoma, lymphoblastic leukaemia or Langerhans Cell sarcoma (Gadner et al, 2001*; Morimoto et al, 2006*; Girschikofsky et al, 2013*).

SUMMARY POINTS

- The Langerhans cell derives from bone marrow dendritic cells and is capable of migrating to the skin and lymph nodes. It is an antigen-presenting cell.
- In Langerhans cell histiocytosis (LCH), the abnormal cells are immature, poorly antigen presenting, and proliferating at a moderate rate. Recent studies have shown the importance of gain-of-function mutations of the BRAF oncogene.
- LCH may present as a single system disease, the most frequent site being an unifocal or multifocal lytic bone lesion.
- Involvement of risk organs (liver, spleen, lungs, bone marrow, endocrine organs, gastrointestinal organs and central nervous system) is associated with a poor prognosis.
- The clinical workup of LCH should include a chest X-ray and a survey of the skeleton: technetium bone scintigraphy screening, completed with X-rays and CT.
- The diagnosis of LCH needs histological confirmation with immunophenotypic marking.
- In cases without risk organ involvement, prognosis (survival) is favourable, independent of the treatment strategy, while risk organ involvement is associated with lack of response, and a higher mortality rate.
- Patients with risk organ involvement are at considerable risk for long term complications.
- LCH is rare in children and is extremely rare in adults.

Part IV: Endocrine diseases

LEARNING OBJECTIVES

- Describe the musculoskeletal features associated with diabetes mellitus (DM)
- Describe the musculoskeletal features associated with thyroid disease
- Describe the management of musculoskeletal features of endocrine disease

I. DIABETES MELLITUS

Diabetes mellitus (DM) is a systemic disease with widespread involvement of different organs. A variety of musculoskeletal conditions have been associated with DM. These conditions are important to recognize because many of them respond to treatment, preventing pain and disability and improving quality of life.

The prevalence of musculoskeletal conditions in patients with DM varies depending upon the definitions used and the study population with DM, which may range from a primary care cohort to patients with severe DM in a specialized academic centre. In contrast to the studied microvascular and macrovascular complications, characterization of the musculoskeletal features associated with DM is derived mainly from observational studies. The pathogenetic mechanism for many of these conditions remained to be elucidated; their association with DM is based largely on epidemiologic data (Crispin JC, 2003; *Lebiedz-Odrobina D 2010,)

I.1 Upper Extremity Manifestations of DM

I.1.1 Carpal tunnel Syndrome

Carpal tunnel syndrome (CTS) is an entrapment neuropathy caused by compression of the median nerve within the carpal tunnel. CTS presents with pain and paraesthesia of the thumb, index and middle fingers and of the radial aspect of the ring finger. Symptoms may be reproduced by percussion of the median nerve at the wrist (Tinel's test) or on wrist dorsiflexion (Phalen's Test). DM is a known risk factor of CTS. DM has been reported in 6 to 17 % in all cases of CTS, and CTS might be more common in those with pre-diabetes (Gulliford MC, 2006). CTS is associated with duration of DM but not with the degree of underlying metabolic control. CTS is more frequent in DM patients with neuropathy. The physiopathology is not fully understood and includes several mechanisms such as increased pressure in the tunnel, median nerve microcirculation injury, median nerve connective tissue compression, and synovial tissue hypertrophy. Local corticosteroid injection and splinting may be beneficial in management though surgery is often required (*Lebiedz-Odrobina et al, 2010).

I.1.2 Flexor tenosynovitis

Flexor tenosynovitis (Trigger finger) is characterized by palpable nodule formation and thickening localized to the flexor tendon or sheath and by the presence of 'locking' phenomena. The ring finger, middle finger and thumb are most often affected and the condition may be bilateral. Flexor tenosynovitis is described up to 12% of diabetic patients (*Cagliero et al, 2002), is more common in type II DM and is associated with duration of the disease but does not seem dependent on glycaemic control. Multiple digit involvement is frequent. Local corticosteroid injection may be beneficial though surgery is often required (Lebiedz-Odrobina D, 2010).

I.1.3 Dupuytren's disease

Dupuytren's disease (DD) is characterized by fibrosis of the palmar fascia, with subsequent nodule formation and contracture of the palmar fascia leading to flexion contracture of the digits. DD is more prevalent in diabetic patients affecting between 16 and 42%, with prevalence increasing with age and duration of diabetes. DD is equally frequent in type I and type II diabetes (Rodrigues et al, 2015). DD is painless and usually not very disabling. Among diabetics, DD most often involves the middle and ring fingers rather than the ring and little finger, as in non-diabetics (*Cagliero E, 2002). Intra-lesional corticosteroid injection and surgery followed by physiotherapy have shown some efficacy. However, recurrence rates are high. Recently, injecting the palmar fascia with collagenase from *Clostridium histolyticum* has been developed as a nonsurgical treatment of DD (Hurst, 2009).

1.1.4 Shoulder pain

Two types of shoulder problems occurs in diabetic patients: Adhesive capsulitis (also known as frozen shoulder) and calcific tendinitis. Adhesive capsulitis has been reported to be twice as frequent in diabetic patients: the prevalence is 10,3% in type I diabetics and 20,4% in type II diabetics. It presents as a painful progressive restriction of range of shoulder motion. Its natural history may be divided into 3 phases: pain, stiffness and recovery. The duration of the symptoms may last an average of 30 months. Increased age and, longer duration of diabetes are associated with capsulitis (Crispin JC, 2003; *Lebiedz-Odrobina D 2010). Analgesics, physical therapy are the first-line of treatment. Intra-articular corticosteroid injections are helpful to obtain short-term pain relief (Roh et al, 2012). Although diabetic patients benefit from arthroscopic release, results from surgery are not as good as in non-diabetic patients, with only 71% of diabetics recovering full range of shoulder movement compared with 90% of non-diabetics in one prospective study (Mehta SS 2014). Calcific tendinitis is a painful condition most commonly affecting the shoulder in which calcium hydroxyapatite crystals deposit predominantly in periarticular areas. The incidence of calcific tendinitis is 31,8% in patients with DM, compared with 10% of non-diabetic patients. Calcific tendinitis may coexist with adhesive capsulitis of the shoulder. Analgesics, physical therapy and intra-articular corticosteroid injections are the standard treatment (Crispin JC, 2003; *Lebiedz-Odrobina D 2010).

1.1.5 Limited joint mobility

Limited joint mobility (LJM), also known as diabetic cheiroarthropathy, is common in patients with DM. It is characterized by limitation of joint movements most marked in the small joints of the hands. It may affect other joints including the metatarsophalangeal and the subtalar joints. Thickening and waxiness of the skin in extremities are also common (diabetic sclerodactyly but the face is spared and there are no telangiectasias). The prevalence of limited joint mobility in DM ranges from 8 to 58% (Gerrits et al, 2015). It occurs in both type I and type II diabetes. The risk increases with increasing glycated haemoglobin (HbA1c) and the duration of DM. There are conflicting data concerning the possible association of limited joint mobility with both

microvascular and other complications of DM. Limited joint mobility is a painless condition and is probably caused by an advanced glycosylation end product on collagen. Patients present generally when stiffness or contractures lead to decreased grip strength and declining dexterity with hand function. Two clinical tests are helpful for diagnosis: the “prayer sign” which is the ability to flatten the hands together as in prayer (figure 1) and the “table top sign” the ability to flatten the palm against the surface of a table. Physiotherapy is the mainstay of therapy (*Lebiedz-Odrobina D 2010).

Figure 1: Positive “prayer sign” test due to limited joint mobility in a diabetic patient

I.2 Lower Extremity Manifestations of DM

I.2.1 Muscle infarction (diabetic myonecrosis)

Spontaneous infarction of muscle is a rare condition which usually affects patients with longstanding and poorly controlled DM. It occurs in both type I and type II diabetes, and the majority of patients have multiple microvascular complications including retinopathy neuropathy and nephropathy. It presents with an acute onset of muscle pain and swelling. There is usually no history of trauma. The swelling may be mildly to extremely tender. The vastus lateralis, thigh adductors, and biceps femoris muscles are most frequently involved but calf or the deltoid muscles may be involved as well. Creatine Kinase levels may be normal or increased. MRI appears to be the most useful diagnostic technique. Differentiation from soft tissue infection and pyomyositis may be difficult and therefore muscle biopsy for bacterial analysis is often performed. Treatment of muscle infarction is symptomatic and includes rest and anti-inflammatory therapy, surgery is not recommended (*Lebiedz-Odrobina D 2010, Trujillo-Santos AJ 2003).

1.2.2 Diabetic amyotrophy (also known as Bruns-Garland syndrome)

Diabetic amyotrophy typically occurs in patients with type II DM that has been recently diagnosed. It is not associated with duration of diabetes. The clinical manifestations include asymmetric focal onset of leg pain which is usually severe, followed by weakness involving the proximal leg, with associated autonomic failure and weight loss. Progression occurs during months and is followed by partial to full recovery in most patients. The diagnosis is based mainly upon the presence of suggestive clinical manifestations in patients with known or newly diagnosed diabetes mellitus. The diagnosis is confirmed with electro diagnostic studies which show axonal degeneration, contrasting with normal spine imaging, with no compression signs. Diabetic amyotrophy is not a pure plexopathy because it also affects the lumbosacral nerve roots and lower extremity peripheral nerves. Occasionally it also affects cervical nerve roots, or upper extremity nerves. The most likely cause is ischemic injury from a non-systemic micro vasculitis causing ischemia in the lumbosacral plexus (Bhanushali et al, 2008). Recovery is rarely complete even if there is a natural improvement of muscle weakness. Ambulatory aids and wheelchair may be needed. Symptomatic treatment including analgesics, narcotics and agents for neuropathic pain may be beneficial (Barohn RJ, 1991). Immunotherapy such as corticosteroids or intra venous immunoglobulins are sometimes discussed, however there is no proof of their efficacy and steroids may aggravate diabetes (Chan et al, 2012).

1.2.3 Neuropathic arthropathy (also known as Charcot osteoarthropathy or Charcot's Joint)

Neuropathic arthropathy is a progressive, degenerative arthropathy associated with various diseases in which severe neuropathy occur. In patients with DM, the loss of sensation may result in a chronic, progressive and destructive arthropathy. DM is the disease most commonly associated with neuropathic arthropathy. The prevalence of neuropathic arthropathy has been reported to be 0.15%. The joints most commonly involved include the ankle, tarso-metatarsal, metatarsophalangeal and toe interphalangeal joints. The pathogenesis remains uncertain though is likely to be due to a combination of mechanical micro traumatisms, bone fragility caused by hyper-resorption, obesity, neuropathic and vascular factors (*Lebiedz-Odrobina D 2010; Papanas et al, 2013).

The diagnosis requires a high index of clinical suspicion. In earlier stages x-rays are normal, while in advanced disease the radiographic features are usually marked (figure 2). Scintigraphic studies and MRI are useful. The diagnosis should always be considered in any patient with diabetes who presents with a unilateral warm, swollen, erythematous foot in the context of peripheral neuropathy and with longstanding diabetes (Lebiedz-Odrobina D 2010). Treatment of neuropathic arthropathy requires a multidisciplinary approach. In early stages immobilization with a cast is recommended. The role of bisphosphonates in management remains unclear (Jude EB, 2001; Parakinen et al, 2013). Surgical correction should be avoided.

Figure 2: Advanced stage of a bilateral Charcot's joints in diabetes: sclerosis and fragmentation is seen

I.3 Spine Manifestations of DM

I.3.1 Diffuse idiopathic skeletal hyperostosis (Forestier Rotes disease)

Diffuse idiopathic skeletal hyperostosis (DISH) is characterized by the calcification and ossification of ligaments and entheses. It affects the axial and appendicular skeleton. The aetiology of DISH is unknown. DISH has been observed more often in diabetics, particularly among patients with type II DM with an estimated prevalence of 13% to 40%. Most patients are asymptomatic; occasionally patients complain of stiffness. Analgesics and exercise have been used to treat patients with DISH (*Lebiedz-Odrobina D 2010).

I.3.2 Osteoporosis

The association between DM and osteoporosis is controversial. Patients with DM have a low turnover in bone formation and to a lesser degree bone resorption. Bone mineral density as measured by DXA is lower in patients with type I diabetes and normal or increased in patients with type II diabetes.(*Shah et al, 2017). One of the reasons seems to be the anabolic effects of insulin, on the bone, thus stimulating osteoblasts. Fracture risk is increased in both groups, although it is not clear whether comorbidities are partially responsible for

increased fracture risk, such as neuropathy, retinopathy, nephropathy or other cardiovascular complications (*de Liefde et al, 2005; *Vestergaard, 2007). There are no specific treatment guidelines for diabetic patients and general guidelines should be followed.

II. THYROID DISEASE

Disorders of the thyroid gland may present with a variety of musculoskeletal symptoms. Conversely, rheumatic diseases may be associated with autoimmune thyroid disease or the presence of antibodies (*Anwar 2010).

II.1 Hypothyroidism

II.1.1 Carpal tunnel syndrome

Unilateral or bilateral carpal tunnel syndrome (CTS) has been reported in hypothyroidism. The mechanism is thought to be due to accumulation of glycosaminoglycans within the carpal tunnel area. CTS is a common entrapment neuropathy with an estimated prevalence of 3.8% in the general population. Electro diagnostic studies are the gold standard for diagnosing CTS. CTS generally improves with thyroid hormone replacement. Local corticosteroid injection and splinting may be beneficial though surgery is often required.

II.1.2 Hypothyroid myopathy

Muscle symptoms may manifest in 25% to 79% of adult patients with hypothyroidism. Symptoms reported by patients include myalgia, cramps, stiffness, fatigability and weakness. It is more common if hypothyroidism is severe or with a prolonged evolution. Symptoms may mimic common rheumatic diseases such as polymyalgia rheumatic and fibromyalgia (*Anwar, 2010). Serum muscle enzymes are frequently mildly elevated in patients with hypothyroid myopathy including creatine-phosphokinase. The physiopathologic mechanism involves an increase in glucoaminoglycan deposition in muscle fibres, sometimes responsible for a pseudohypertrophy. Calves and forearms are the most frequently affected. There are numerous reports in the literature of polymyositis like illnesses associated with hypothyroidism. Diagnosis is supported by electromyography studies which helps to differentiate thyroid myopathy from other myopathies. Muscle biopsy is not usually indicated. There is a favourable prognosis with hormone replacement, although clinical and biological improvement can take several months to be observed.

II-1-3 Bone metabolism.

In paediatric patients, cases of growth retardation are possible. In adults, if hypothyroidism is severe, bone turnover is decreased, but bone mineral density measures may be decreased or normal or increased. Increased fracture risk is suspected in hypothyroid patients, even in case of subclinical hypothyroidism (Yang et al, 2017).

II.2 Hyperthyroidism

Hyperthyroidism may be due to several causes, including autoimmune, drug induced or iatrogenic disease. Grave's disease is the most common cause of autoimmune hyperthyroidism worldwide (*Anwar 2010).

II.2.1 Myopathy

Hyperthyroid myopathy has a similar presentation as hypothyroidism: proximal weakness, myalgia and fatigability. In contrast with hypothyroidism, serum CK levels are normal; furthermore myopathic changes on EMG are rare. Muscle biopsy is not necessary to confirm the diagnosis except if an associated auto-immune disease is suspected with inflammatory myopathy. Two unusual manifestations of hyperthyroidism (commoner in the past) were associated with rheumatic complaints: pretibial myxoedema and thyroid acropachy. Pretibial myxoedema is asymptomatic and is manifested as skin induration over the pretibial area. Thyroid acropachy is characterized by clubbing of the finger and toes. Both conditions are associated with thyroid ophthalmopathy (*Anwar 2010).

II.2.2 Bone metabolism

Patients with untreated hyperthyroidism have an increase bone turnover and net loss of bone mass. In a meta-analysis the risk of fracture was increased in patients with hyperthyroidism (Vestergaard P, 2003). Hyperthyroidism is a classical cause for secondary osteoporosis, and should be considered in every osteoporotic patient. Hypercalcemia and hypercalciuria may also be present. Bone involvement is reversible, when patients regain normal thyroid function, bone mineral density increases to normal values, although the process may take more than a year.

II.2.3 Other

Auto-antibodies are the hallmark of autoimmune disease and patients suffering from Hashimoto's Disease or Graves' Disease are at higher risk to develop other auto-immune mediated diseases. Some of these associated auto-immune diseases, such as lupus, rheumatoid arthritis, celiac disease, and myasthenia are responsible for musculoskeletal involvement and must not be mistaken for an atypical manifestation of thyroid disease. (*Anwar et al, 2010; Boellaeert et al, 2010)

IN-DEPTH DISCUSSION I

Gaucher's disease

INTRODUCTION

Gaucher disease (GD) is the most common lysosomal storage disease. It is caused by deficiency of glucocerebrosidase, which results in abnormal accumulation of glycolipids within cellular lysosomes. As the risk of skeletal disease with irreversible complications is reduced with early initiation of enzyme replacement therapy, rheumatologists should be alerted to splenomegaly or hepatomegaly of unknown cause in presence of bone disease and/or unexplained.

GD is an autosomal recessive disorder in which gene mutations on chromosome 1q22 lead to decreased activity of the hydrolytic enzyme glucocerebrosidase in all cells of the body. Three different clinical types can be distinguished, the adult non-neuropathic form (Type 1) is the most common type and occurs predominantly in Ashkenazi Jews. More than 95% of GD patients have type 1 disease.

Table I: Epidemiology of Gaucher disease

Peak age	Any age from birth to old age
Gender distribution	1:1
Prevalence	1/57000 births, more common in Ashkenazi Jews
Transmission	Autosomal recessive

CLINICAL MANIFESTATIONS OF TYPE 1 GAUCHER DISEASE

Symptomatic patients have mainly visceral involvement, bone disease and bleeding. Splenomegaly and hypersplenism leads to cytopenias. Bone marrow infiltration leads to osteopenia, fractures and bone pain.

The major clinical manifestations are depicted in table II.

Table II

Clinical Manifestation	Frequency at presentation (%)
Splenomegaly	85
Hepatomegaly	63
Thrombocytopenia	68
Anaemia	34
Bleeding	Common
Osteopenia	55
Bone pain	33
Pathologic fractures	7
Bone crisis	7
Growth retardation	36

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of GD depends upon the presenting symptoms and signs. Splenomegaly and thrombocytopenia can result from many disorders, namely leukaemia, lymphoma, rheumatoid arthritis or other storage diseases such as Niemann-Pick. On the other hand osteopenia, pathologic fractures, osteonecrosis and bone pain are features of a variety of diseases.

Table 3: Differential diagnosis of radiologic features of type 1 Gaucher disease

Erlenmeyer flask deformity	Diffuse or localized osteopenia
Niemann-Pick disease	Osteoporosis (idiopathic, corticosteroid induced)
Pyle disease	Hyperparathyroidism
Fibrous dysplasia	Hemoglobinopathies
Hyperthyroidism	Neoplastic disorders (multiple myeloma)
Haemolytic anaemias (thalassemia)	
Leukaemia	
Osteopetrosis (Albers-Schönberg disease)	
Heavy metal poisoning	
Rachitism sequelae	
Fracture sequelae	
Osteosclerosis	Osteonecrosis
Osteosclerotic skeletal metastasis	Hemoglobinopathies (sickle cell anaemia)
Phacomatosis (tuberous sclerosis)	Hypercorticism
Osteopetrosis	Caisson disease
Mastocytosis	Collagen vascular disorders
Osteomyelofibrosis	Pancreatitis
Hodgkin's disease	
Hemoglobinopathies	

MANAGEMENT

The current recommendations for the initial evaluation of Type 1 GD have been elaborated by the Gaucher registry coordinators:

1. History and pedigree
2. Comprehensive physical examination

3. Quality of life questionnaire
4. β -Glucocerebrosidase activity and genotyping
5. Primary blood test: haemoglobin and platelets
6. Biochemical markers of the disease: chitotriosidase, angiotensin converting enzyme and plasma tartrate resistant acid phosphatase
7. Additional blood test: white cell count, haemostasis testing, serum immunoelectrophoresis, liver enzymes, calcium and phosphorus values
8. Assessment of visceral involvement: spleen and liver (MRI or CT)
9. Assessment of skeletal involvement
 - a. Radiographs of the femora and spine
 - b. MRI of the entire femora
 - c. Dual energy x-ray absorptiometry of the lumbar spine and femur
10. Assessment of cardio-pulmonary involvement: electrocardiogram, chest radiograph, Doppler echocardiogram for measurements of right ventricular systolic pressure.

THERAPEUTIC GOALS

Following a consensus conference, treatment goals in Gaucher's disease are increasing survival, prevention of irreversible damage, elimination of symptoms, and improvement of overall health and quality of life. The following goals for skeletal involvement are recommended:

- Lessen or eliminate bone pain within 1-2 years
- Prevent bone crisis
- Preventing osteonecrosis and subchondral joint collapse
- Improve bone mass

TREATMENT

As many therapies are now available, choosing the right one (ERT or SRT) is a new challenge.

Enzyme replacement therapy (ERT) has been used for more than two decades. Three forms of macrophage targeted glucocerebrosidase are now available (imiglucerase, velaglucerase alfa and taliglucerase alfa). Glucocerebrosidase infusions reverse the haematological complications and hepatosplenomegaly within 12-20 weeks although bone response requires a longer period. Bone pain, bone crisis and osteonecrosis are reduced. Low dose or intermittent dose regimens fail to achieve sustained improvement and treatment for 2-3 years is currently recommended.

Substrate reduction therapy (SRT) is an oral alternative treatment. Miglustat, an iminosugar that decreases substrate synthesis, is approved for patients with mild to moderate GD 1 who are intolerant of imiglucerase. Eliglustat, a ceramide analogue that inhibits glucosylceramide synthase, has been recently approved as a first line treatment for adults (> 18 years) with GD1 who are CYP2D6 extensive, intermediate or poor metabolizers. Substrate reduction therapy reduces hepatic and splenic volume, the incidence of bone pain and also increases platelet counts.

Symptomatic treatments with bone remodelling drugs (alendronate) and orthopaedic surgery are often required. Splenectomy is rarely considered now that enzyme therapy is available.

IN-DEPTH DISCUSSION II

Screening for hereditary haemochromatosis

Introduction:

Hereditary haemochromatosis (HH) is defined as the phenotypic expression of iron overload due to mutations in the HFE gene on both copies of chromosome 6 (Pietrangelo, 2010). This leads to excessive absorption of iron from food. In Western Europe over 90% of patients with HH are homozygous for the C282Y mutation of the HFE gene and another 4% are compound heterozygotes (C282Y/H63D). There are other rarer forms of HH where patients have 'classical' clinical features of haemochromatosis but lack known mutations in the HFE gene.

Table 1: Reversibility of HH features by phlebotomy

Reversible manifestations
• Heart: cardiomyopathy, conduction disturbances
• Liver: elevated liver function tests, hepatomegaly
• Skin: bronzing (melanin deposition), grey pigmentation (iron deposition)
• Infection: <i>Vibrio vulnificus</i> , <i>Listeria monocytogenes</i> , <i>Pasteurella pseudotuberculosis</i>
Irreversible manifestations
• Liver: cirrhosis, hepatocellular carcinoma
• Pituitary gland: gonadotropin insufficiency leading to secondary hypogonadism*
• Pancreas: diabetes mellitus
• Thyroid gland: hypothyroidism
• Genitalia: primary hypogonadism
• Joints: arthropathy, CPP deposition

Without treatment, excessive iron storage cause hepatic cirrhosis and other serious conditions including diabetes, cardiomyopathy and arthritis. HH becomes symptomatic from the age of around 40 onwards. Routine bloodletting to maintain appropriate serum iron levels is a simple yet effective means by which to prevent these complications. However, in symptomatic HH patients bloodletting is not completely curative. Some symptoms are (partly) reversible, while others manifestations are irreversible (see table 1). Taking into account that mortality in HH is highly correlated with the presence of irreversible manifestations like diabetes and liver cirrhosis this pleads for prevention.

Prevention

Prevention of HH-related morbidity and mortality warrants an early diagnosis. Since people homozygous or compound heterozygotes for the HFE gene mutation comprise 90% or more of the HH patients, accounting for approximately 6‰ of the general population, population screening is an option. Even more, screening of the first degree relatives of a symptomatic HH patient is highly effective. However, the disease shows relatively low penetrance, and many homozygotes never develop clinical symptoms. So demonstration of genetic susceptibility for HH will alarm many people who are unaware of possible disease and some never will become symptomatic. Indeed in studies on population or family screening for HH the willingness to participate was

limited and anxiety increased. The acquaintance with the disease HH, probably explains the higher willingness for participation in family studies (over 50%) as compared to studies in the general population (approximately 25%). Although not intended, the knowledge of having the HFE gene mutation even in the absence of increased serum iron concentration might have negative consequences for employability as well as for insurability. Although the relevant legislation differs across countries, and in many parts of Europe discrimination based on available genetic data is prohibited, negative consequences cannot be excluded totally.

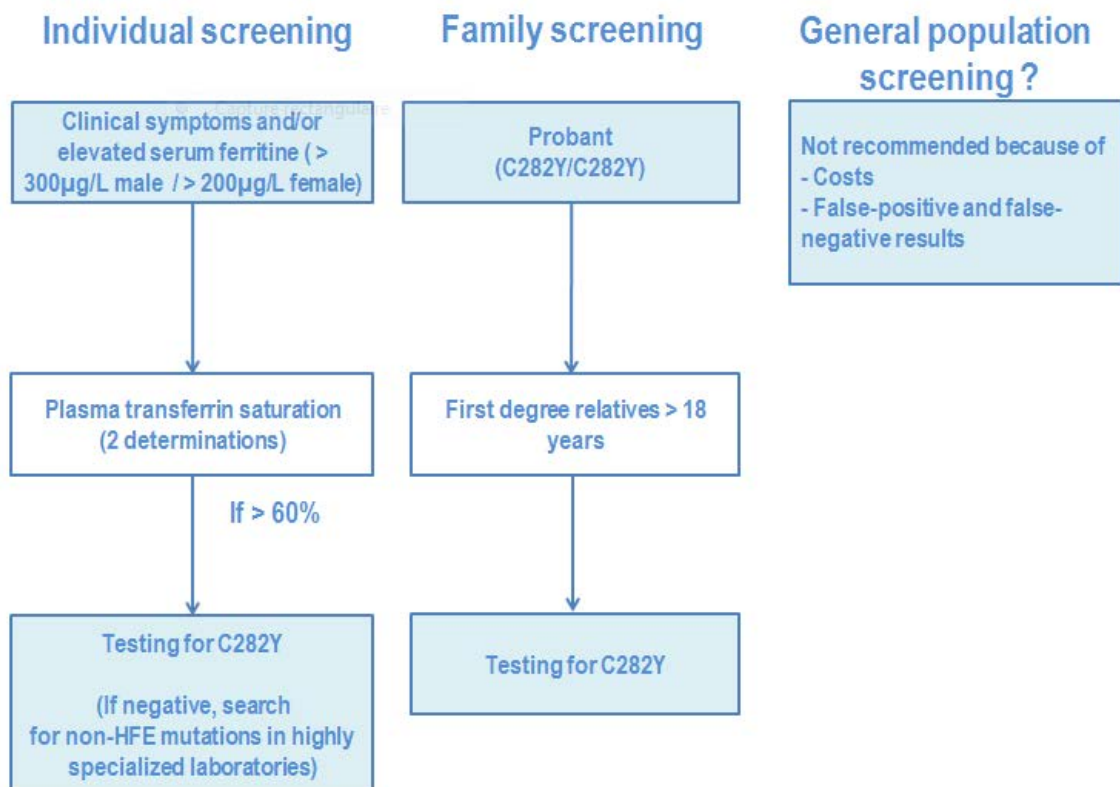

General population screening:

Population screening for HH has been recommended by some authors, due to the high prevalence of the mutant allele coupled with the low cost and high efficacy of early diagnosis and treatment compared with that for late-stage diagnosis. However, even for a simple genetic condition like HH, screening the general population is not straightforward. Since characterization of the HFE gene in 1996 (Feder et al, 1996), genetic testing has become available.

A person carrying two copies of the C282Y mutation or the compound heterozygote combination C282Y/H63D is at risk of developing iron overload and subsequent disease. However, like all diseases, HH is not only defined genetically and not every patient with the HFE mutation will develop the disease. At present it is difficult to predict if an individual patient with a HFE mutation will ever become symptomatic. The key factors in considering population screening are whether it will do more benefit than harm and whether it is cost-effective.

The present available genetic tests identify nearly 95% of patients with HH permitting early identification of those at risk for iron overload.

If the clinical penetrance is such that the majority of people who are C282Y homozygous eventually accumulate iron, the most logical approach will be to screen all adults by genetic testing and to follow those at risk by measuring ferritin or transferrin saturation at 3-yearly intervals (See fig 1). However, in non-northern European populations, HH is rare and the C282Y mutation is not associated with the disease so testing the general population would be inappropriate, and additional decisions may have to be made about selective testing. Moreover, even in the northern European population, the clinical penetrance is low, so a systematic genetic screening could lead to incorrect diagnosis in many people. This could be harmful and cause problems with obtaining medical insurance. The population genetic screening is therefore not recommended because it could lead to more harms than benefits (EASL, 2010; Whitlock et al, 2006; Powell et al, 2016; Brissot et Loréal, 2016). The alternative, regular testing of transferrin saturation or ferritin concentration, provides many false positive results as well as false negative results (subjects with mutation of the HFE gene who have not yet accumulated iron).

Figure 1: Algorithm genetic testing for HFE mutation.

Family screening

Screening first degree relatives of patients diagnosed with HH is another option.

The value of testing for the C282Y mutation in relatives remains unclear, because of the unknown risk of developing clinical disease in C282Y homozygotes. Disease penetrance in the absence of comorbid factors may be low, although the iron overload of first degree relatives with the genotype at risk may be predicted by the disease severity in the index patient (Powell et al, 2016; Brissot et Loréal, 2016). Moreover, the acceptability of the test is certainly better in relatives of an affected patient than in the population at large and the overall efficiency of the test to detect HH patients is much better in relatives than in the population at large, as C282Y homozygotes are much more frequent. The current standard of care is therefore to propose screening of first degree relatives for the C282Y mutation (EASL, 2010), by informing the affected patient of the availability of the test and asking him to inform his relatives. Because the first symptoms develop in adulthood, the choice of testing in children is usually postponed until they become adult and can decide for themselves (Brissot et Loréal, 2016; Porto et al 2016). For patients with two or more children, the most cost-effective approach may be to test the patient's spouse first, and to then test the children only if the spouse is heterozygous. For one child, direct testing is more cost-effective (El-Serag et al, 2000). C282Y homozygotes should undergo monitoring of their iron parameters (serum transferrin saturation and serum ferritin) and phlebotomy should be started if iron overload develops (fig 1). The value of testing for other mutations than C282Y is more

arguable, because the chance of finding the H63D mutation is high, as its population frequency is 20 %, and because documented iron overload in C282Y/H63D compound heterozygote is rare (Gurrin et al, 2009).

Conclusion

Early diagnosis of HH is of the outmost importance, since the prognosis of the disease is much improved by early treatment. The rheumatologist has here a key role to play as joint involvement is frequently an early feature of the disease. Once the diagnosis is made he has to inform his patient about the availability of family screening and the opportunity to prevent development of the disease in his family.

Skin and auto-immune rheumatic diseases

Dan Lipsker, Cédric Lenormand and Franco Rongioletti

A previous version was coauthored by Camille Francès, Elisa Cinotti, Franco Rongioletti

LEARNING OBJECTIVES

- Identify the different types of skin manifestations in lupus erythematosus
- Assess the risk of systemic involvement in the different variants of cutaneous lupus erythematosus
- Identify possible conditions associated with subacute cutaneous lupus erythematosus
- Initiate treatment of skin manifestations in patients with lupus erythematosus
- Identify thrombotic vascular skin lesions in patients with systemic lupus erythematosus
- Identify skin lesions in dermatomyositis
- Correlate some of the dermatomyositis skin manifestations to a specific antibody profile and/or systemic disorder
- Identify type of skin involvement in the different forms of scleroderma
- Identify skin manifestations found in systemic vasculitis
- Recognize the most frequent and the most typical skin lesions of the different systemic vasculitides
- Assess skin conditions associated with rheumatoid arthritis and Still's disease
- Identify the cutaneous side effects of antirheumatic drugs including biologics

This chapter focuses on cutaneous manifestations observed in autoimmune rheumatic diseases, particularly lupus erythematosus (LE), dermatomyositis (DM), scleroderma, the main systemic vasculitides and rheumatoid arthritis. Clinical correlation between these manifestations and internal organ involvement is highlighted. See box 1 for definitions of skin manifestations.

Box 1 Definitions

- Alopecia: absence of hair from a normally hairy area
- Aphtha: small superficial and painful white ulceration of the mucosa, single or multiple, round or oval, lasting 7 to 14 days and healing without scarring (syn.: canker sore)
- Atrophy: thinning of normal skin. It may affect the epidermis, dermis or subcutaneous tissues.
- Bulla: rounded protrusion due to accumulation of fluid within or beneath the epidermis (greater than 0.5 cm to 1 cm in diameter)
- Ecchymosis (bruise): area of cutaneous haemorrhage more than 2 mm in diameter; usually this term is employed when referring to large (> 2 cm) lesions.
- Erosion: superficial loss of epidermis, which heals without scarring. It commonly follows a blister.
- Erythema: redness of the skin produced by vascular congestion or increased numbers of capillaries
- Excoriation: linear erosion or ulcer produced by scratching
- Exfoliation: splitting off the epidermal keratin in scales
- Fibrosis: formation of excessive fibrous tissue; this is a pathological finding and its most common clinical consequence is induration of skin sometimes also referred to as sclerosis, though the usage of this latter term should also be restricted to pathology reports.
- Fissure: any linear gap or slit in the skin surface
- Keratoderma: horny thickening of the skin, usually referring to palms and/or soles
- Macule: circumscribed alteration in the colour of the skin. It can be any colour or shape.
- Milium: tiny white cyst in the epidermis containing keratin
- Nodule: solid mass in the skin, more than 1 cm in diameter. It may involve the epidermis and dermis, dermis and hypodermis, or hypodermis alone.
- Papule: circumscribed palpable elevation, less than 1 cm in diameter
- Petechia: punctate haemorrhagic spot, approximately 1–2 mm in diameter
- Plaque: elevated area of skin, 1 cm or more in diameter, usually flat. It may be formed by the extension or coalescence of papules.
- Purpura: haemorrhagic area in the skin. Purpura does not blanch when touched. Petechia and ecchymoses are variants of purpura.
- Pustule: vesicle filled with pus
- Scale: flat plate or flake of stratum corneum (adjectives: scaling and squamous, but the latter term is usually restricted to histopathological descriptions)
- Scar: replacement by atrophic and/or fibrous tissue of another tissue that has been destroyed by injury or disease
- Ulceration: loss of epidermis and dermis, often with loss of the underlying tissues; if chronic: ulcer
- Vesicle: small bulla, less than 0.5 to 1 cm in diameter
- Weal: circumscribed, often confluent papule or plaque because of dermal oedema, white or reddish, compressible and per definition transient

1 Skin manifestations in lupus erythematosus

Skin manifestations are a main feature of lupus erythematosus (Werth, 2007*). They are present in more than 80% of cases. The Systemic Lupus International Collaborating Clinics (SLICC), an international group focused on systemic lupus erythematosus (SLE) clinical research, revised the American College of Rheumatology (ACR) classification criteria for SLE in 2012 (Petri et al, 2012*; Yu et al, 2014*).

Notably, 4 of the 11 clinical criteria for SLICC are dermatological criteria:

1. Acute or subacute cutaneous lupus erythematosus; also included: bullous SLE, toxic epidermal necrolysis variant of SLE
2. Chronic lupus erythematosus (CLE): numerous clinical variants
3. Oral (or nasal) ulcers
4. Non-scarring alopecia

Skin lesions of patients with LE can be divided into 4 groups (Lipsker, 2010*): specific lesions of lupus erythematosus, lesions reflecting thrombotic vasculopathy/vasculitis, neutrophilic cutaneous lupus erythematosus and miscellaneous lesions associated with lupus erythematosus. Lupus erythematosus should be considered as a continuous spectrum of variants with single organ lesions such as cutaneous lesions at one end (but renal variants also exist) and serious multi-organ disease at the other.

A precise dermatological diagnosis is very important as skin features not only help to identify the disease, but can also in many cases bear prognostic signification and involve specific therapeutic interventions.

1.1 Specific lesions of lupus erythematosus

They allow establishing a diagnosis of LE even when the ACR/SLICC criteria are not met, by clinico-pathological correlation of the organ skin. This is possible because all these so-called *specific lesions* display a common histopathological finding, namely an *interface dermatitis*. The latter corresponds to a lymphocytic infiltrate in the upper dermis, at the dermal-epidermal junction, with vacuolization of keratinocytes, keratinocyte necrosis, pigment incontinence and epidermal atrophy. Definition of the type of specific lesion should take into account the appearance, the site and the course of the lesion, its histological findings as well as the associated systemic signs and immunological abnormalities. Specific lupus lesions were traditionally separated in three main entities, namely acute, subacute and chronic lupus erythematosus (Walling and Sontheimer, 2009*). However, this does not reflect the more complex reality and a comprehensive and practical classification based on clinico-pathological correlation on one hand, and highlighting the importance of thrombotic and neutrophilic lesions on the other, has been proposed (Lipsker, 2010*). This newer classification is now increasingly

accepted. This classification separates the specific lesions according to the main level of anatomical skin involvement: dermo-epidermal, dermal and hypodermal. For historical reasons, the three main types of dermo-epidermal CLE will be first reviewed in detail.

1.1.1 Acute cutaneous lupus erythematosus

1.1.1.1 Clinical features

A *congestive erythema*, often mildly raised, mostly without skin surface alteration, with ill-defined borders, is the primary lesion of acute CLE. Acute cutaneous lupus erythematosus (ACLE) has one of the following presentations: malar erythema (does not count as SLICC criteria if chronic lupus erythematosus is also present), maculo-papular rash (mainly on photo-exposed areas), bullous lesions, and a toxic epidermal necrolysis (TEN)-like lupus rash. In ACLE, the lesions tend to be transient, following sun exposure; itching does usually not occur but a burning sensation is sometimes reported. An erythematous slightly oedematous rash over the cheeks, sparing the nasolabial folds, and across the bridge of the nose (a malar or 'butterfly' rash) is the most typical eruption. This localised eruption may also affect the forehead, the peri-orbital area, the neck and the low neckline (figure 1). In contrast to discoid LE, atrophy and follicular plugging are absent.

Figure 1 Oedematous and erythematous 'butterfly' rash. Patient consent obtained.

Figure 2 Macular lesions over the dorsum of the hands.

A more diffuse eruption can sometimes occur, mainly after sun exposure, with pruriginous maculo-papular lesions, especially above the waistline and resembling a drug reaction. Some scattered macular lesions can also be found over the dorsum of the hands (figure 2). Dermatomyositis (DM) should be excluded, but LE classically respects the articular surfaces of the back of the fingers, that are typically involved in dermatomyositis. Photosensitivity alone without skin lesions is no longer a diagnostic criterion for SLE because although it is present in about 60% of patients with SLE, it can be also found in normal subjects (20% of healthy people in Sweden), and it is difficult to establish a consensual definition.

Occasionally, *blistering* may complicate very acute forms, with bullous lesions predominating on erythematous skin (figure 3). This must be distinguished from bullous SLE, which is the consequence of a neutrophilic dermal infiltrate and not an interface dermatitis. Rarely, widespread erythema with a positive Nikolski sign (skin detachment on pressure) mimicking TEN is found in hypercube variants of LE. Erosive *oral lesions* are frequent, especially in case of renal involvement. The numerous types of bullous lesions and surface alterations in LE have been extensively reviewed by Merklen-Djafri et al. (2015*).

Figure 3 Bullous lesions in extremely acute lupus erythematosus.

All ACLE lesions heal without scarring, but sometimes with dyspigmentation.

1.1.1.2 Differential diagnosis

ACLE can be clinically confused with various facial dermatoses, especially rosacea (figure 4) characterised by telangiectases, with papules and pustules that are not found in ACLE, and with seborrheic dermatitis (figure 5) that mainly affects the naso-labial folds. Those 2 disorders are extremely common (2 to 3% of the general population). DM should be also considered in the differential diagnosis, but it is characterised by more intense purplish-red erythema and oedema of the upper eyelids, and DM lesions often itch. Both lupus erythematosus and DM can present with lesions on the dorsal aspect of the hands; in lupus erythematosus, the lesions mainly affect the inter-articular skin, while in DM they affect the skin over the joints.

Figure 4 Rosacea. Patient consent obtained.

Figure 5 Seborrheic dermatitis. Patient consent obtained.

Widespread eruption can resemble contact dermatitis, viral exanthema or a drug reaction.

1.1.2 Subacute cutaneous lupus erythematosus

1.1.2.1 Clinical features

Subacute cutaneous lupus erythematosus (SCLE) has two clinical subtypes: the maculo-papular lesions can present with 1) an annular shape or 2) a psoriasis-like pattern. In the first case, the lesions are polycyclic. Borders are erythemato-squamous and may show vesiculation and crusting. They surround a grey-white hypopigmented and teleangiectatic area (figure 6). In the psoriasis-like pattern, lesions are papulo-squamous (figure 7). Both manifestations can be seen in the same patient and the relevance of this distinction is thus low. SCLE lesions are superficial without prominent follicular plugging or hyperkeratosis. This type of cutaneous lupus is usually very photosensitive, with lesions confined to sun-exposed skin. However, the midfacial skin is usually spared, while the sides of the face, the V of the neck, the upper trunk, and extensor aspects of the upper extremities are commonly involved.

Figure 6 Subacute annular cutaneous lupus erythematosus lesions.

Figure 7 Subacute psoriasis-like cutaneous lupus erythematosus lesions.

Lesions can frequently leave pigmented or hypopigmented macules and telangiectases, but usually resolve without scarring, in contrast to the situation in discoid lupus erythematosus (DLE).

Oral erosive lesions are less frequent and do not correlate to any internal involvement.

1.1.2.2 Differential diagnosis

Differential diagnoses include dermatophytosis, nummular eczema, erythema multiforme, psoriasis, pityriasis rosea and drug eruption. Histological examination can easily distinguish SCLE from all these dermatoses except from drug eruption and a huge number of SCLE flares are triggered by drugs, especially calcium-channel inhibitors, proton-pump inhibitors, terbinafine and hydroxychlorothiazide.

1.1.2.3 Associations

- In approximately 80% of patients with SCLE, anti-Ro/SS-A antibodies are found on ELISA, immunoblot or more sensitive solid phase immunoassays.
- Newborns with neonatal lupus and many patients with inherited complement deficiencies have the same clinical SCLE features. Neonatal lupus erythematosus is a form of SCLE that occurs in newborns

whose mothers have anti-Ro/SS-A autoantibodies and usually manifests with erythematous annular patches, with the butterfly rash or with cardiac conduction abnormalities.

- SCLÉ is frequently (up to 50% of patients) associated with Sjögren's syndrome.
- Drug-induced lupus presents most frequently with SCLÉ lesions, therefore a careful drug history must always be performed (see 1.1.8).

1.1.3 Chronic lupus erythematosus

Discoid lupus erythematosus (DLE) is the most common type of chronic LE. Typical DLE (figure 8) demonstrates well-defined plaques with 4 primary lesions.

Two are features of active lesions:

- Erythema with well-demarcated borders and sometimes central telangiectasias;
- Adherent scales (keratosis) with follicular plugging, thus a rough surface on palpation.

Two others reflect damage:

- Atrophy, with a thinning of the skin that becomes fragile and translucent, and
- Pigmentary changes where hypo- and hyperpigmentation can coexist.

Lesions are often multiple and symmetrical. They are mainly localised on UV-exposed areas, especially over the bridge of the nose, the cheeks, the ears and the side of the neck. Even unexposed areas like the eyebrows, eyelids and scalp can be affected. Involvement of the scalp can be found in up to 60% of patients with DLE and are they are the only manifestation in 10% of cases, causing permanent cicatricial alopecia (figure 9). Lesions resolve leaving a sepia coloured hyperpigmentation.

DLE can be localised or disseminated. Localised DLE affects the head and the neck, whereas disseminated DLE extends to other areas of the body such as the trunk and the limbs, particularly the elbows and the dorsa of the hands and feet, especially in patients with complement deficiencies. Lesions of the palms and soles are erosive, painful and extremely disabling; they can evolve into a scleroderma-like atrophy of the digit. Nail changes are rare and occur with lichen-like dystrophies. Oral lesions have clinical and histological features hard to distinguish from lichen planus, i.e. white papules on a red atrophic background with irradiating white striae on the border.

Figure 8 Discoid lupus erythematosus.

Figure 9 Scarring alopecia in discoid lupus erythematosus.

Hypertrophic (or verrucous) DLE is an unusual variant characterised by thick scaling/keratosis over the discoid lesion or occurring at the periphery of the discoid lesion. The lesions are often located on the extensor arms, but the face and upper trunk may also be involved. Some variants are indistinguishable from inflammatory keratoacanthoma centrifugum marginatum.

1.1.4 Other forms of dermo-epidermal lupus (indeterminate lupus, chilblain lupus, bullous lupus)

1.1.4.1 Indeterminate lesions of lupus erythematosus (Sontheimer RD, 1997*)

This entity first described by Sontheimer corresponds to isolated erythematous plaques often located on the trunk, devoided of clinical characteristics of either ACL, SCLE or DLE (scaling, atrophy, follicular plugging), but with a typical histological aspect of interface dermatitis.

1.1.4.2 Chilblain lupus erythematosus

Chilblain LE (fig 10) can correspond to 2 situations. First, acral located LE lesions, with a typical interface dermatitis, but mimicking clinically chilblain. Second, chilblain lesions without interface dermatitis, where lesions can't be distinguished from idiopathic chilblain / perniosis (i.e. erythematous or purplish, infiltrated papules or plaques localized on fingers, toes, ears and nose). In this case, helpful clues to separate those 2 entities are: the persistence of the lesions during the warm season clinically and vacuolization of keratinocytes pathologically which, if present, are suggestive of chilblain LE while oedema, spongiosis and perieccrine infiltrate are more common in classic pernio. Chilblain LE is frequently associated with DLE lesions, and also with systemic signs of LE in approximately 20% of cases; it is difficult to treat and poorly responsive to antimalarials (Chasset et al, 2017). Confusion with “vasculitis” is frequently made by non-dermatologists.

Familial chilblain lupus is a monogenic form of cutaneous LE resulting from mutations of genes involved in the activation of type 1 interferon (*TREX1*, *SAMDH1*, *STING*), exemplifying the concept of interferonopathy.

Figure 10 Chilblain lupus erythematosus.

1.1.4.3 Bullous lupus erythematosus

Bullous LE is a rare auto-immune blistering disease affecting young adults and sometimes children with a known SLE. It is characterized by the presence of antibodies directed against collagen VII, an important component of the cutaneous basement membrane. Bullous LE manifests as tense vesicles or bullae on a normal or erythematous background, located on the trunk and extensor aspect of the limbs, without significant pruritus. Mucosa can be involved, especially the lip. Lesions spontaneously heal without scarring, but hyper- or hypopigmentation is generally present and may take months to resolve.

Bullous LE is a neutrophil-mediated form of cutaneous lupus and dapsone is the treatment of choice, not antimalarials.

1.1.5 Dermal lupus erythematosus

Dermal LE is a spectrum of lesions with consistent overlap that share clinical and histological characteristics, associated with a rather good prognosis as in DLE, even if rare aggressive systemic complications may occur. The spectrum of dermal lupus erythematosus encompasses a rather cellular form of dermal LE, with dense “sleeve-like” perivascular and periadnexal infiltrate, with no or slight mucin deposition (Jessner type) to a paucicellular form with substantial mucin deposition and no or slight infiltrate (papulonodular mucinosis type/cutaneous lupus mucinosis type).

1.1.5.1 Lupus tumidus (sometimes referred to as intermittent lupus erythematosus)

Lupus tumidus (figure 11) is characterised by sharply demarcated red-purple oedematous plaques in sun-exposed skin of the face and the upper trunk, without scale or follicular plugging. Those lesions are usually highly photosensitive. Healing occurs without scarring or alopecia.

Figure 11 Sharply demarcated red-purple oedematous plaques. Patient consent obtained.

1.1.5.2 Jessner's lymphocytic infiltrate of the skin

JLI is another variant of dermal LE which typically presents with multiple red papules and plaques with frequent annular or arciform configuration and/or arrangement, without scale or follicular plugging and less prominent oedema than lupus tumidus. Lesions are located on the head, neck and upper part of the thorax. Distinction with borreliac lymphocytoma may be difficult. It is often not possible to distinguish JLI from lupus tumidus.

1.1.5.3 Cutaneous lupus mucinoses (papulonodular mucinosis, reticulate erythema with mucinosis/REM)

Both entities are histologically characterized by abundant interstitial deposits of mucin, with a less prominent lymphocytic infiltrate (figure 12). Papulonodular mucinosis present with red firm nodules sometimes resulting in non-scarring alopecia on the scalp. REM present with reticulated pink to red macules or flat plaques on the chest with symmetrical distribution and midline involvement. For some authors, REM should not be considered as a variant of lupus erythematosus, but as a separate entity (Cinotti E et al, 2015*).

Figure 12 Papular mucinosis in systemic lupus erythematosus.

1.1.6 Hypodermal lupus (lupus panniculitis)

Lupus erythematosus profundus or lupus panniculitis (figure 13) is a rare hypodermic manifestation of LE. It appears as single or multiple indolent to sometimes painful subcutaneous plaques or nodules that may sometimes ulcerate, which evolve to a characteristic cupuliform depression resulting from secondary atrophy of the subcutaneous tissue (figure 14). The main localisations are the upper arms, the shoulder girdle, the breast in women, as well as the thighs and cheeks. In 70% of cases, lupus panniculitis is associated with DLE lesions, and systemic involvement may occur in approximately 40% of patients. Differential diagnoses include all other types of panniculitis and nodular vasculitis.

Figure 13 *Lupus panniculitis.*

Figure 14 *Atrophy in lupus panniculitis.*

1.1.7 Pathology

The various clinical cutaneous types of dermo-epidermal lupus erythematosus show a similar histological picture with interface dermatitis of the vacuolar type and a superficial and deep peri-vascular and peri-adnexal lymphocytic infiltrate in the dermis. Epidermal colloid bodies, corresponding to apoptotic keratinocytes, can be found, especially in SCLE. Interstitial mucin deposition is a good diagnostic clue. The level and intensity of

this infiltrate depend on the subtype, being more intense and deep in DLE than in ACLE. A progressive thickening of the basement membrane is present, which is best seen with a PAS stain.

In ACLE, there is a pronounced oedema of the superficial dermis with liquefying degeneration of the basal cell layer of the epidermis that may lead to blistering in very acute lesions. Hyperkeratosis is not prominent. The mononuclear infiltrate is moderate and often peri-vascular. ACLE can resemble DM on histological features and direct immunofluorescence can show deposits of IgM and C3 in both diseases, although the presence of immunoglobulins and complement at the dermo-epidermal junction in non-lesional skin is found only in ACLE.

In SCLE, epidermal colloid bodies are seen with slight hyperkeratosis and a moderate mononuclear lymphocytic infiltrate. Histological changes may be confused with those of drug eruption.

In DLE, marked orthokeratotic hyperkeratosis is present with plugging of the follicular ostia. A dense dermal lymphocytic infiltrate, particularly present around the appendages, can extend to the lower dermis and lead to skin atrophy. Usually there is less basal vacuolar change, dermal oedema and dermal mucin than in ACLE, and there is more lymphocytic infiltrate compared to ACLE.

In bullous LE, biopsy from fresh vesicles typically shows junctional blistering associated with a neutrophil-predominant infiltrate in the dermis, without interface dermatitis but with sometimes mucin deposits as a useful clue to the diagnosis.

In dermal lupus (lupus tumidus being the most frequent variant), the epidermis is usually normal without interface dermatitis or if present, it is very mild. The lymphocytic infiltrate is found in the upper and lower dermis in a peri-vascular and peri-adnexal distribution with frequent dermal deposits of mucin.

In lupus panniculitis, the epidermis and dermis may or not have a DLE appearance, which is a help to the diagnosis if present. The hypodermis shows a striking lobular infiltrate of lymphocytes, plasma cells and histiocytes along with nuclear debris, fibrinoid deposits, mucin accumulation, hyalin necrosis of adipocytes and septa hyalinisation. Fibrosis and calcification can occur.

Direct immunofluorescence (DIF) shows linear or granular immunoglobulin (IgG, IgA or IgM) and/or complement (C1q, C3) deposits at the dermo-epidermal junction in 80–90% of cases of ACLE and DLE, 70% of cases of panniculitis and 60% of cases of SCLE (figure 15). In lupus tumidus, direct immunofluorescence may be negative. These deposits, however, are not specific to lupus erythematosus and can be found in DM, some cases of rosacea and on normal sun-exposed skin of 20% of the population (especially IgM). We thus do not use DIF in our routine daily practice because of this low positive predictive value, except for the diagnosis of bullous LE.

Figure 15 Positive direct immunofluorescence in lupus erythematosus.

1.1.8 Laboratory investigations

Lupus erythematosus is characterised by the presence of circulating antinuclear antibodies (ANA). These are rarely found in DLE, but are almost always present in ACLE and in SCLE.

In particular, anti-double strand DNA (dsDNA) antibodies are specific for lupus erythematosus and can also be found in early subclinical cases, antihistone antibodies are a sign of drug-induced lupus and usually disappear 1 year after the causative drug has been discontinued, while anti-La/SS-B and anti-Ro/SS-A antibodies are mostly related to SCLE and Sjögren's syndrome. Anti-collagen VII antibodies may be evidenced by specific ELISA or immunoblotting, with positive results in approximately 70% of patients with bullous LE.

Antiphospholipid antibodies are also frequently found in lupus (Frances et al, 2005*).

Low complement levels (C3, C4, CH50) may be associated with congenital deficiencies of certain fractions or related to consumption, the latter being suggestive of progression to systemic lupus erythematosus.

1.1.7 SLE and the different types of skin lupus

The relationships between the main types of skin lupus and SLE are summarised in table 1.

Table 1 Relationships between the main types of specific skin findings and systemic lupus erythematosus

Type of skin lupus	SLE association (%)	% Of different skin manifestations in SLE series
ACLE	90	60–80
SCLE	50	7–21
DLE	20	20
Panniculitis	40	2–3

ACLE, acute cutaneous lupus erythematosus; DLE, discoid lupus erythematosus; SCLE, subacute cutaneous lupus erythematosus; SLE, systemic lupus erythematosus.

All types of skin lupus can be associated with SLE to varying degrees (table 1). Thus, more than 90% of patients with ACLE have or will develop SLE, skin manifestations being inaugural in 50–60% of cases. Inversely, 60–80% of patients with SLE had or have ACLE lesions. These lesions very often develop together with systemic flares so that organ involvement must be searched for thoroughly.

According to the ACR/SLICC criteria, more than 50% of patients with SCLE have SLE. In fact, most patients with SCLE do not have severe systemic involvement that would justify treatment with systemic steroids or immunosuppressive treatment. Severe and life-threatening renal or neurological conditions can be found in only 10% of patients with SCLE. Inversely, 7–21% of patients with SLE have SCLE lesions.

Overall, 10–20% of patients with DLE have or will develop SLE and 15–30% of those who have SLE present DLE skin type lesions, which are inaugural in 5% of cases. Premenstrual or gestational flares as well as disseminated DLE might increase this risk.

About 40% of patients with lupus panniculitis could develop SLE. However, panniculitis is reported in less than 3% of patients with SLE.

1.1.8 Drug-induced lupus erythematosus

Similar to idiopathic lupus erythematosus, drug-induced lupus erythematosus (DILE) can manifest with ACLE, SCLE and DLE lesions; SCLE lesions are the most frequent. The drugs most often implicated in the development of ACLE-type lesions are hydralazine, procainamide, isoniazid and minocycline and the recently reported tumour necrosis factor (TNF)- α antagonists. Most cases of DILE induced by anti-TNF- α antagonists are caused by infliximab, followed by etanercept and adalimumab. Drugs associated with SCLE include calcium channel blockers, angiotensin-converting enzyme inhibitors, thiazide diuretics, terbinafine, carbamazepine, statins, proton pump inhibitors and TNF- α antagonists. Drug-induced DLE is very rarely described in the literature and usually associated with fluorouracil agents, methimazole or TNF- α antagonists. Moreover, anti-TNF- α antagonists frequently induce the production of ANA and anti-dsDNA autoantibodies without clinical signs of LE.

The typical laboratory profile of acute DILE consists of positive ANA and antihistone antibodies, the latter being regarded as the serum marker of this subset, whereas in drug-induced SCLE ANA and anti-Ro/SSA antibodies are present but antihistone antibodies are uncommon. In drug-induced DLE, ANA are usually negative. If DILE is clinically possible, drug discontinuation may help alleviate LE and also serve as a diagnostic test, whereby LE improvement would suggest the drug has a role. Most DILE cases spontaneously resolved within weeks of drug withdrawal, but autoantibodies could be present for months after treatment discontinuation.

1.1.9 Other associations

All cutaneous forms of lupus erythematosus can be associated with other autoimmune systemic diseases, but at unknown frequencies.

Some 3–50% of patients with SCLE develop Gougerot-Sjögren syndrome with an increased frequency in patients over 55 years of age. This association increases the risk of cutaneous vasculitis, central nervous system involvement and interstitial pulmonary syndrome. Annular eruptions reported in the Japanese literature to be associated with Gougerot-Sjögren syndrome and anti-SS-A, SS-B antibodies may resemble lupus tumidus lesions.

1.1.10 Treatment of lupus erythematosus lesions

European guidelines on the treatment of cutaneous lupus erythematosus have been recently published (Kuhn et al, 2017*), though the suggested strategy is not the one performed in most French reference centres. Sun protection is extremely important in all types of lupus. All patients should be advised to wear a broad-brimmed hat and avoid short-sleeved shirts and shorts. Moreover, sunscreen should be used permanently even when sun exposure is not expected. Patients should repeat sunscreen application every 2 hours when in the sun as the sun protection factor (SPF) does not take immersion or sweating into consideration. SPF 50 sunscreens and light reflecting sunscreens providing greater protection against UVA and UVB are more effective. However, it is also important to consider the risk of vitamin D deficiency in sun-avoiding patients, as sunlight is required for vitamin D synthesis. 25-Hydroxyvitamin D levels should be monitored and supplementation with vitamin D3, or cholecalciferol, is advised. Cessation of smoking is important, as cigarette smoking is an established risk factor of cutaneous lupus. Avoidance of mechanical stress (isomorphic trigger factors) should be recommended.

Topical treatment is frequently used as a first-line therapy in limited lesions (Walling and Sontheimer, 2009*), though it is rarely sufficient. It can be combined with antimalarials in case of partial response or diffuse lesions. High-potency steroid creams are effective, but should be avoided as long-term treatment of facial lesions.

Tacrolimus and pimecrolimus, two topical immunomodulators, are moderately effective in SCLE and lupus tumidus. Topical retinoids are of help in hyperkeratotic lesions.

Antimalarials are first-line treatment for cutaneous lupus erythematosus (Chang and Werth, 2011*).

Hydroxychloroquine (HCQ) and chloroquine sulfate (CQS) are most widely used. HCQ is often preferred to CQS since it is thought to cause less ocular toxicity and blood dosages to assess efficacy are more easily available. Efficacy assessment should be performed after 4 to 6 months of treatment, when clinical improvement is expected in more than 60% of patients (Chasset et al, 2017). The mechanism of action of oral antimalarials in skin lupus is not exactly known and probably includes photoprotection as well as anti-inflammatory and immunological effects. HCQ should be maintained during pregnancy where it prevents flares. As the most serious side effects are ocular manifestations and regular ophthalmological follow-up to detect toxicity before significant vision loss is essential. In the revised American recommendations on screening for CQS and HCQ retinopathy (Marmor et al, 2016*), the recommended dosage of HCQ to minimize ocular toxicity is ≤ 5.0 mg/kg real weight, and CQS ≤ 2.3 mg/kg real weight (which is inferior to the widely use dosing of 6.5 mg/kg for HCQ and 4 mg/kg for CQS). A baseline eye examination is required during the first year of treatment, with annual screening starting only after 5 years of treatment in the absence of major risk factors (box 2). The baseline screening should include automated visual fields and spectral-domain optical coherence tomography (SD-OCT). These examinations may be completed with tests not widely available such as multifocal electroretinogram and fundus autofluorescence. The frequency and type of eye examinations used in screening for retinopathy are determined by ophthalmologists and vary by country. HCQ and CQS should never be combined because of enhanced ophthalmological toxicity.

Box 2 Recommendations for ophthalmological screening of patients treated with antimalarials

Frequency of evaluation

First year of use: fundus examination, completed with visual fields and SD-OCT if abnormalities

Annually after 5 years in low-risk patients:

- daily dosage of HCQ ≤ 5.0 mg/kg real weight (≤ 2.3 mg/kg real weight if CQS)
- normal glomerular filtration rate
- no concomitant tamoxifen use
- no pre-existent macular disease

More frequent in patients with major risk (frequency to be determined by the ophthalmologist):

Examination by the ophthalmologist

Examination should include assessment of:

- automated visual fields (wider test patterns are needed for Asian patients);
- SD-OCT

SD-OCT: spectral-domain optical coherence, HCQ: hydroxychloroquine, CQS: chloroquine

Other side effects include pigmentation of the oral mucosa (figure 16), nails and legs, greying of the hair and, less commonly, aquagenic pruritus, urticaria, maculo-papular rash and vasculitis. If patients do not respond to

antimalarials, they may not have taken the medication as prescribed e.g. because of nausea or the bitter taste of antimalarials. Assessing blood levels of HCQ is very useful before concluding treatment ineffectiveness. Sun exposure, smoking and drug interactions may be associated with a lack of response. Exchanging HCQ for CQS or vice versa may improve the response. Adding quinacrine 100 to 200 mg/day to HCQ could also be another therapeutic option. However, about 15–20% of patients are refractory to antimalarials.

Figure 16 Palatal pigmentation in hydroxychloroquine treatment.

Thalidomide is used in some European countries, including France, as a second-line treatment at an initial dose of 100 mg/day followed by a minimal effective maintenance dose. Open studies show that the remission rate is above 70% after 3 months of treatment. However, the drug effect is only moribund. Strict contraceptive measures must be taken by fertile women starting therapy after a menstrual period, because of the drug's high teratogenicity. Procreation is not allowed, even in men. Thalidomide can also cause sleepiness, weight gain, amenorrhea, impotence, thrombotic complications, and mainly distal polyneuropathy with a risk of irreversible neurotoxicity. Therefore, a monthly neurological follow-up and a bi-annual electromyography are recommended, and thromboprophylaxis (i.e. low molecular weight heparin and/or aspirin) should systematically be discussed. Though not approved in this indication, low-dose (5 mg/d) lenalidomide is as efficient as thalidomide, but with a much better tolerance.

When skin lupus is resistant to antimalarials and there are contraindications for thalidomide, the therapeutic decision becomes more difficult. It is essential then to weigh the benefits and risks before choosing any further medication. Systemic glucocorticoids are usually not indicated in skin lupus. They are ineffective at low doses and their use is restricted due to known side effects at high doses impeding subsequently long-term treatment.

Dapsone at 100–150 mg/day may help some patients with cutaneous lupus erythematosus, and is the first-line drug in neutrophilic LE, including bullous SLE (see 1.3). Lower doses (<100 mg/day) may be sufficient in SCLE. Consequently, toxicity risks are diminished, particularly dose-dependent haemolysis and methaemoglobinemia. Concomitant intake of folic acid improves dapsone tolerance.

Sulfasalazine (1.5 or 2 g/day) has been reported to help in more than 50% of patients with DLE. However, multiple side effects were noted; some were particularly severe like hypersensitivity syndrome and lupus aggravation and its use is therefore no more recommended.

Immunosuppressors like azathioprine, methotrexate, mycophenolate mofetil, and rituximab have been prescribed in anecdotal cases with variable results, methotrexate and mycophenolate mofetil being those recommended as second- and third-line agents by recent European guidelines ((Kuhn et al, 2017*).

Intravenous immunoglobulins are expensive and irregularly effective.

Oral retinoids (mainly acitretin) are an alternative therapy in antimalarial-refractory DLE, especially the hyperkeratotic variant. As these agents are highly teratogenic, it is critical to ensure the use of effective contraception in women of childbearing potential, both during and after treatment (1 month for isotretinoin and 2 years for acitretin). Retinoids can also cause hyperlipidaemia and hepatotoxicity; therefore, careful monitoring of lipids and liver function tests is necessary during treatment.

Belimumab, a monoclonal human antibody that inhibits B lymphocyte stimulating protein (BLyS), is the first biologic agent approved for the treatment of SLE by the US Food and Drug Administration and the European Medicines Agency. Belimumab is recommended in combination with standard treatment in adult patients with SLE with high disease activity (defined, for example, by the presence of anti-native DNA antibodies and low complement) despite standard treatment (antimalarials, glucocorticoids and/or immunosuppressants) in the absence of kidney or central nervous system involvement or severe autoimmune thrombocytopenia. Although it has been demonstrated that this drug has some efficacy on cutaneous lupus erythematosus (unspecified skin rashes, alopecia and mucosal ulceration), belimumab is so far not recommended for the forms of lupus that are limited to the skin. The recommended dosage is 10 mg/kg intravenously on days 0, 14 and 28 and then every 4 weeks. Administration of belimumab may cause severe hypersensitivity infusion reactions. Therefore, belimumab should be administered in hospital and patients should remain under medical supervision for several hours after the first two infusions. Discontinuation of belimumab should be considered in the absence of disease control after 6 months of treatment. Belimumab has not been well studied in pregnancy or breastfeeding in humans, and should be not recommended in these cases.

A variety of other monoclonal antibodies including TNF- α blockers, epratuzumab (which blocks the CD22 antigen, an extracellular molecule that regulates B cell activation and interaction with T cells), tocilizumab (which blocks the IL-6 receptor), abatacept (which blocks the links between antigen-presenting cells and T cells) and atacicept (which blocks two B cell activating factors, BLyS and APRIL) have also been used in relatively small numbers of SLE patients with variable benefit. These biologics are not yet approved for the treatment of SLE and their efficacy on skin manifestations should be assessed. TNF- α blockers have been used

in some cases of CLE and SCLE with efficacy, but it should be noted that they can also induce a lupus-like syndrome as a side effect.

1.2 Lesions indicative of a thrombotic vasculopathy/vasculitis

The presence of vascular manifestations in lupus erythematosus may reflect distinct pathological processes. If genuine vasculitis can occur, mainly under the form of urticarial vasculitis (see 1.3), it is of uttermost importance to identify skin lesions reflecting an underlying thrombotic pathomechanisms, as it may be part of a potentially life-threatening thrombotic process necessitating anticoagulation, mainly –but not exclusively- in the context of the antiphospholipid antibodies syndrome.

1.2.1 Livedo

In SLE, livedo especially of the racemosa type (figure 17) is significantly associated with secondary antiphospholipid syndrome, thrombo-embolic arterial events (hypertension, cerebral ischaemic manifestations, and seizures) and thickened cardiac valves. It is less frequently reported when sole venous thrombosis occurs. Mottling is red, thin, particularly diffuse (trunk and limbs), not infiltrating, and looks like an incomplete net with an apparently branching configuration (livedo racemosa). It differs from the livedo associated with vasculitis which is infiltrated and mainly located on the legs. It also differs from cholesterol emboli livedo which is purplish, painful, and usually associated with skin necrosis. A skin biopsy taken from a livedoid area is frequently normal. If deep and wide-enough, it may show a proliferative endarteritis.

Figure 17 Livedo racemosa in systemic lupus erythematosus.

1.2.2 Lesions reflecting dermal micro-infarction (petechial purpura, 'atrophie blanche' and 'pseudo-Degos' papules, splinter haemorrhages of the nail)

Petechial purpura with variable necrosis is generally reflecting the thrombotic microangiopathy of lupus. It is observed on the tips of digits and toes, on the ankles and elbows.

'Atrophie blanche' and lesions similar to those of malignant atrophic papulosis (Degos' disease) (figure 18) are also usually subsequent to a thrombotic process and frequently seen in patients with positive antiphospholipid antibodies.

Figure 18 *Papule with depressed white centre and raised red border similar to malignant atrophic papulosis.*

The sudden onset of multiple splinter haemorrhages under the nails of several fingers in SLE patients is often concomitant with a systemic event like deep thrombosis or a systemic flare (figure 19). 'Haemorrhages' is an improperly used term because the pathological process usually consists of micro-thromboses; embolic or vasculitic aetiology is less common.

Figure 19 *Splinter haemorrhages of fingernails in systemic lupus erythematosus.*

1.2.3 Extensive skin necrosis and peripheral gangrenes

Extensive skin necrosis (figure 20) begins with widespread angular purpura of the limbs, the buttocks and the face (cheeks, ears and nose) that rapidly evolves into large areas of gangrene edged by a purpuric border. Biopsy of this area reveals thrombotic vessels. Anti-coagulation with heparin is the mainstay of treatment. Prostacyclin-derived vasodilators can be added. Plasmapheresis may be useful when life-threatening

complications of the antiphospholipid syndrome are present. Peripheral gangrene (mainly of digits) may be present.

Figure 20 Widespread purpura in systemic lupus erythematosus.

1.2.4 Anetoderma

The term anetoderma refers to circumscribed areas of slack skin associated with a loss of dermal substance on palpation and a loss of elastic tissue on histological examination (figure 21).

Lesions of variable number and size are mainly located on the neck, upper trunk and upper limbs. In lupus erythematosus, anetoderma is correlated with the presence of antiphospholipid antibodies and thus likely reflects underlying thrombosis.

Figure 21 Anetoderma in chronic lupus erythematosus.

1.2.5 Leg ulcers

Up to 3% of patients with SLE develop leg ulcers. Arterial and venous Doppler ultrasonography of the lower limbs must be performed and a skin biopsy of the ulcer border discussed, especially in the absence of macrovascular anomaly. The leg ulcer may be the result of either immune-complex-mediated vasculitis or,

more commonly, deep or superficial thrombosis. It is therefore more frequent in patients with antiphospholipid antibodies.

1.3 Neutrophilic cutaneous lupus erythematosus

A number of neutrophilic dermatoses may occur in patients with SLE, a general feature that is likely to reflect the involvement of auto-inflammatory processes in the pathogeny of lupus erythematosus. Identifying such conditions and underlying pathomechanisms is crucial, as immunosuppressive agents are usually not helpful and associated with overtreatment; instead anti-neutrophil drugs such as colchicine and dapsone are the treatment of choice. Bullous LE (already treated in 1.1.4.3) is a good example of this important distinction.

Besides bullous lesions, other skin signs that should suggest neutrophilic lupus erythematosus are urticarial lesions or pustular lesions.

1.3.1 Urticarial lesions (*urticarial vasculitis and neutrophilic urticarial dermatosis*)

The presence of urticarial lesions (figure 22) has been reported in 4–13% of patients with SLE, encompassing different nosological situations. Acute or chronic histamine-mediated idiopathic urticaria is possible in LE patients, sometimes drug-induced, responding well to anti-histamine H1 therapy. Urticarial lesions may also reflect small-vessel vasculitis, namely urticarial vasculitis, where authentic leucocytoclastic angiitis is present when histology is performed, generally accompanied by low complement levels and anti-C1q antibodies, as part of the McDuffie syndrome. Angioedema may be present in both histamine-mediated urticarial and urticarial vasculitis, however acquired C1 inhibitor deficiency or ACE-related angioedema should always be ruled out.

A distinctive picture of rose to red macules or slightly elevated papules with only minimal itching characterized histologically by an intense neutrophilic interstitial, perieccrine and perivascular infiltrate with leucocytoclasia but without fibrinoid necrosis of vessel walls has been termed 'Neutrophilic urticarial dermatosis'. This new entity first described in 2009 generally occurs in association with SLE (Gusdorf et al, 2014), but also with other systemic diseases such as Still's disease, Schnitzler syndrome or cryopyrin associated syndromes. The form associated with SLE may also rarely show an interface vacuolar alteration on histological examination.

Figure 22 *Urticaria in systemic lupus erythematosus.*

1.3.2 *Amicrobial pustulosis of skin folds*

Aseptic pustulosis of the folds is a well delineated clinical picture also belonging to the neutrophilic dermatoses spectrum. It has been reported in SLE and other autoimmune diseases. It manifests with aseptic pustules on an erythematous background of erosive evolution in the main skin folds, with highly suggestive scalp and external ear meatus involvement. Pustules are spongiform on histology. Oozing infections can complicate cruro-genital pustulosis (figure 23). Zinc deficiency was found in some cases. Systemic glucocorticoids are the most effective treatment, but colchicine and dapsone should be tried first. Anakinra and TNF alpha inhibitors may represent interesting alternatives in refractory cases or when steroids are contra-indicated, though a similar clinical picture can be induced by TNF inhibitors, as part of a so-called paradoxical reaction, in a few patients with inflammatory bowel disease or ankylosing spondylitis.

Figure 23 *Aseptic pustulosis of skin folds.*

1.4 Other miscellaneous lesions associated with lupus erythematosus

These skin manifestations represent a heterogeneous group of skin lesions found in patients with SLE, but devoid of well-identified significance.

1.4.1 Acral syndromes and other vascular signs

Raynaud's phenomenon, not so severe as in scleroderma, is present in 10–45% of patients with SLE and can occur a long time before other skin manifestations. Specific treatment such as calcium channel blockers and ACE inhibitors is rarely required.

Erythromelalgia (functional peripheral vascular disease associated with erythema, swelling and pain of the extremities) may be a presenting feature in SLE. Aspirin should be used as a first line treatment, and clonazepam has been reported as efficient in case reports; however, many patients will not be alleviated by treatment.

Palmar erythema and dilation of the nail fold capillaries frequently occur in SLE, resembling those seen in scleroderma and DM. Megacapillaries on capillaroscopy of the nail folds are found in 10% of SLE patients.

1.4.2 Diffuse non-scarring alopecia

Unlike in DLE where alopecia in involved areas is scarring and permanent, diffuse loss of hair occurs in SLE, especially in the active phase of the disease or, less frequently, 3 months later (figure 24). Hair recovers as the disease becomes inactive. Moreover, the hair is usually fine and growth slow, producing a band of short broken-off hair on the frontal margin (lupus hair).

Figure 24 Diffuse hair loss in systemic lupus erythematosus.

1.4.3 Calcinosis

Calcinosis in cutaneous LE is rare. Deposits can be palpable under lupus lesions or in normal skin. Mixed connective tissue disease and anti-RNP antibodies must be ruled out.

In conclusion, clinical analysis of skin manifestations in lupus erythematosus supported by histological examination facilitates a precise diagnosis, a very important step before initiating appropriate therapy. The practical classification presented here is synthesized in table 2.

Table 2 Skin manifestations in lupus erythematosus, with their significance (according to Lipsker, 2010)

Skin manifestations	Systemic involvement	Significance
Specific signs of LE		Allows to establish a diagnosis of LE ("specific" signs)
<i>Dermo-epidermal LE</i>		
- Acute	Frequent	
- Subacute	Less aggressive, anti-Ro +	
- Chronic discoid	Rare	
- Indeterminate	Possible	
- Bullous	Possible	
<i>Dermal LE</i>	Possible, but rare	
- Tumidus		
- Jessner's lymphocytic infiltrate of the skin		
- Lupic mucinoses		
<i>Hypodermal (subcutaneous) LE</i>	Possible	
- Panniculitis		
Signs indicative of a thrombotic vasculopathy	Present. Always search for underlying antiphospholipid syndrome	Important prognostic and therapeutic implications
- Dermal micro-infarctions		- Optimization of cardiovascular risk factors
- Peripheral gangrene, skin necrosis		- Discontinuation of oestroprogestative contraception
- Livedo reticularis		- Antiplatelet / anticoagulation therapy
- Acral non-infiltrated purpura		
- Anetoderma		
- Thrombophlebitis		
Neutrophilic LE	Present	Different pathophysiology implying different therapeutic approaches
- Bullous LE		
- Urticarial neutrophilic dermatosis		- Anti-neutrophil drugs (colchicine, dapsone)
- Urticarial vasculitis		
- Amicrobial pustulosis		
Miscellaneous	Present	Unknown
- Eruptive fibromas		

-
- Raynaud's phenomenon, erythromelalgia
 - Interstitial granulomatous dermatitis, rheumatoid nodules
 - Leukocytoclastic vasculitis
 - Non-scarring alopecia
 - Calcinosis
 - Histamine-mediated urticaria
 - ...
-

2 Skin manifestations in dermatomyositis

Skin signs in more than 50% of patients precede muscular manifestations by 3–6 months. They can be either typical or less characteristic and barely different from those seen in other autoimmune diseases, especially lupus erythematosus. DM skin features can be divided, as in LE, into three groups: specific DM lesions with interface dermatitis on histology, non-specific vascular lesions, and other non-DM-specific lesions.

2.1 DM-specific skin lesions

2.1.1 Clinical features

In 30–60% of cases, the face shows a purplish-pink oedema typically involving the upper eyelids and peri-orbital skin (figure 25). The violaceous lesions around the eyes reminded early clinicians of the colour of a heliotrope flower, and were thus referred to as heliotrope erythema. Heliotrope erythema can be found to a lesser extent on the cheeks, nose (sparing the tip and bridge), forehead, temples and ears. The peri-oral area and naso-labial folds are usually spared. Oedema is firm and of variable intensity. It can generate a burning sensation and even obscure the erythema, especially in African patients.

Figure 25 Heliotrope erythema. Patient consent obtained.

On the dorsum of the hands, small, erythematous, finely scaling papules/plaques occur as linear streaking over the extensor tendon sheaths with obvious reinforcement on the dorsal and lateral sides of metacarpophalangeal and interphalangeal joints (Gottron sign). Similar skin involvement can be seen on the outer aspects of the elbows, knees and, less commonly, the malleola.

Flat, infiltrated, purplish papules (Gottron papules) occur frequently with erythema (figure 26). They appear on the dorsum of finger joints and around the nails and are considered pathognomonic of DM. Sometimes, these papules become atrophic with pigmentary changes and telangiectases leading to poikiloderma. Erythema of the palmar folds of the fingers is a rare but very characteristic sign of DM, apparently related to mucin skin deposits.

Widespread, symmetrical, purplish-red plaques are frequent in DM. They occur on the neck, limbs, anterior chest (often in a V sign) or on the back and shoulders (the shawl sign). They may be aggravated after exposure to the sun. When heliotrope erythema is missing, these diffuse lesions may resemble photodermatitis, contact dermatitis or LE. Moreover, the scaling aspect of some lesions may suggest the incorrect diagnosis of LE or seborrheic dermatitis. Linear erythematous streaks on the trunk and proximal extremities, known as flagellate erythema, are almost specific for DM (the only differential diagnoses being flagellate dermatitis consecutive to bleomycin administration or improperly cooked shiitake intake and fixed lesions observed in some patients with Still's disease). Bilateral, symmetrical, reticulate, sometimes poikilodermatous lesions of the lateral aspects of the thighs and hips (holster sign) are another sign suggesting DM.

Wong-type DM (figure 27) is characterised by follicular, erythematous and keratotic papules of the outer aspects of the limbs with palmar or less commonly diffuse keratoderma. It occurs more frequently in adults and children of Eurasian origin.

Figure 26 Gottron papules.

Figure 27 Follicular, erythematous and keratotic papules in Wong-type dermatomyositis.

Lateral and palmar areas of the fingers may become rough and cracked, with irregular dirty horizontal lines, resembling a mechanic's hand (figure 28). These mechanic's hands are found in the so-called anti-synthetase syndrome, which is serologically characterised by the presence of aminoacyl-tRNA synthetase autoantibodies and clinically by myositis, eczematous inflammatory skin changes as well as interstitial lung disease. In this type of DM, minimal muscle involvement should not lead to underestimation of disease severity since the risk of pulmonary fibrosis is high, and around 21% of patients die within 5 years.

Figure 28 Mechanic's hand.

The essential features of poikiloderma are atrophy, hyper or hypopigmentation and telangiectasia. The upper trunk (shoulders, upper back, and low neckline) and buttocks are frequently affected, in an asymmetrical pattern. Poikiloderma often follows the purplish plaques after a long natural course or treatment response. It can be, however, an inaugural manifestation of DM (poikilodermatomyositis) where differential diagnoses are radiodermatitis, T cell lymphoma (especially mycosis fungoides), LE or congenital forms of poikiloderma.

Scalp involvement is relatively common with diffuse erythematous-squamous lesions, poikiloderma and mild to moderate non-scarring alopecia.

Vesiculo-bullous, ulcerated or necrotic lesions can occur and point to a potential underlying malignancy. The histological picture variably associates vasculitis with severe interface dermatitis.

Erythroderma is the term applied to extended (> 90% of body surface) scaling, oedematous and persistent erythema with general malaise, thermoregulation abnormalities, and dermopathic lymph nodes. It is very uncommon in DM, so a relationship with poor prognosis or increased associated risk of an underlying malignancy cannot be established.

Panniculitis lesions are rare in DM. Deep, firm and painful nodules affect the arms, buttocks, thighs and abdomen. They can precede, accompany or follow initial signs of the disease. With interface vacuolar dermatitis, the subcutaneous fat shows a lobular lympho-plasmocytic infiltrate, sometimes with membranocystic changes.

Mucous membrane lesions such as bright red oral erythema and erosive genital lesions are rare.

2.1.2 Differential diagnosis

The cutaneous lesions of DM can be distinguished from those of lupus erythematosus by their characteristic violaceous colour and the tendency of lesions to be distributed around the eyes and on extensor surfaces. Moreover, the lesions on the backs of the hands are usually located over the joints in DM but in the spaces between the joints in lupus erythematosus.

Erythematous scaling plaques seen on the outer aspects of the elbows and knees can be misdiagnosed as psoriasis.

Clinically, Wong-type DM resembles pityriasis rubra pilaris but histological features are characteristic with follicular hyperkeratosis over a piloerector muscle myositis.

2.1.3 Pathology

DM lesion histology is not specific since some LE lesions demonstrate almost identical features: hyperkeratosis, epidermal atrophy, interface dermatitis with vacuolar changes in the basal cell layer, oedema of the superficial dermis, dilation of capillaries, pigmentary incontinence, and sometimes mucin deposits. The peri-vascular, inflammatory infiltrate consists of neutrophils and activated CD4 lymphocytes. Turgescient endothelial cells, vessel dilation and fibrin deposits in the vessel wall are frequently found. The presence of leucocytoclastic vasculitis might increase the risk of an associated malignancy. Positive direct immunofluorescence in affected skin is a statistically significant, distinctive criterion distinguishing between LE and DM: linear deposits of IgG or C3 at the dermo-epidermal junction are found in 90% of LE lesions but in only 10–20% of DM lesions.

2.1.4 Laboratory investigations

DM is characterised by myositis-specific autoantibodies (anti-Mi2, anti-MDA5, anti-RNA synthetase, anti-hPMS-1, anti-NXP2, anti-TIF-1 gamma, anti-SAE) and myositis-associated autoantibodies (anti-Ro/SSA, anti-PM/Scl, anti-Ku), the latter occurring also in autoimmune diseases without myositis and thus most frequently reflecting overlap syndrome. These antibodies are helpful as they are associated with distinctive clinical and evolutive features (Fujimoto et al. 2016*)

The anti-Mi2 antibodies are the most common myositis-specific autoantibodies found in these patients and are associated with an increased prevalence of cutaneous lesions and with a good response to therapy. The MDA-5 (melanoma differentiation-associated gene 5) antibodies, originally called CADM-140 (clinically amyopathic dermatomyositis antibody, 140 kD), are associated with amyopathic DM, pulmonary involvement and papules of the palms, digital ulcers and oral ulcerations or pain. Some 20% of patients have anti-RNA-synthetase antibodies, which include for example anti-Jo1, PL7 and PL12 antibodies and define the anti-synthetase syndrome, characterised by myositis, pulmonary fibrosis, Raynaud's phenomenon, non-erosive arthritis and mechanic's hand. Anti-synthetase syndrome may thus represent a distinct entity within the inflammatory myositis spectrum. The anti-TIF-1gamma and to a lesser extent anti-NXP2 antibodies (in adults) are clearly associated with an underlying malignancy, which should be actively monitored in this subgroup of patients for extended duration.

2.1.5 Treatment

No specific treatment is required for skin lesions since healing often occurs when myositis is treated, though this is not obligatory. Myositis and muscle enzymes often respond faster than the DM skin changes to high-dose or pulse treatment with glucocorticoids, immunosuppressants or intravenous immunoglobulins. However, affected skin should be treated in amyopathic DM and in isolated skin recurrences. Treatment is then similar to first-line treatment in LE, i.e. antimalarials, as skin signs alone do not justify the use of high-dose systemic steroids. Methotrexate and IgIV are alternatives.

Photoprotection is essential since the skin may be photosensitive. Daily use of topical steroids can help in limited moderate lesions (Callen and Wortmann, 2006*), but should be avoided on the face because of cutaneous atrophy and the risks of steroid-induced rosacea. Response after 6 weeks of tacrolimus 0.1% ointment or pimecrolimus 1% cream use is variable. HCQ is frequently prescribed as a first-line treatment (Quain and Werth, 2006*) at a dose of 200–400 mg/day with or without topical steroids; efficacy is variable. CQS was also used at a dose of 100–250 mg/day. When previous treatments fail, dapsone, mycophenolate mofetil, methotrexate and cyclophosphamide can be used. Thalidomide is not effective. High-dose intravenous immunoglobulins are frequently successful as second-line treatment especially when glucocorticoids are contraindicated, but their high cost may restrict their use.

2.2 Vascular lesions

Congestive well-demarcated erythema of finger or toe nail folds is characteristic. It is the result of vascular involvement and is often associated with thickened, haemorrhagic cuticles and macroscopic megacapillaries. The nail fold becomes painful when the cuticle is pressed or pushed back (manicurist sign).

Moderate Raynaud's phenomenon occurs in 10–15% of adult DM and is very rare in childhood DM. Onset may occur many years before cutaneous changes.

Cutaneous thrombosis and vasculitis are mainly reported in DM with an underlying malignancy or another associated autoimmune disease.

2.3 Other non-specific lesions

Pruritus and a burning skin sensation are frequent in DM. Secondary excoriations can also be found. Pruritus and a burning sensation may help distinguish DM from LE where it is rarely noted; it sometimes predicts the presence of an associated malignancy especially when very intense.

Photosensitivity occurs in 30% of cases necessitating sun protection.

Calcinosis represents a major clinical problem in DM and is more frequent in children (especially in association with anti-NXP2 antibodies) than in adults (30–70% vs 10%). It can affect the skin, aponeuroses and muscles. Common sites include the proximal joints of the limbs, axillary folds, and the hips and bony prominences of the elbows and knees. The notion that DM calcinosis spares distal finger joints and finger pads, which are frequently involved in systemic sclerosis, is most often but not always true. However, it can become a source of constant pain and discomfort. Early and intensive treatment of DM may partially prevent these calcifications. However, once calcinosis is present, treatment is disappointing. Colchicine (1 mg/day), warfarin, diltiazem, aluminium hydroxide, probenecid and alendronate have been used with anecdotal success. Surgery is the treatment of choice when feasible, especially in localised cutaneous calcifications.

2.4 DM sine myositis

DM sine myositis or amyopathic DM is defined as typical clinical and histological cutaneous DM lacking clinical or enzymatic muscle involvement even after 2 years of follow-up. A small subset of patients (2–18%) never develops myositis, despite having prominent cutaneous changes. The risk of underlying malignancy is similar to that in other types of DM. In some patients, myositis resolves with treatment but cutaneous disease persists as the most important feature. These cutaneous lesions are sometimes refractory to standard treatment such as topical glucocorticoids and HCQ. Topical calcineurin inhibitors are sometimes effective. Thalidomide is ineffective.

2.5 Childhood DM

Skin manifestations in childhood DM are similar to those in adults. Nevertheless, onset is insidious causing delay in diagnosis. They frequently begin with a persistent, telangiectatic, erythema around the nails.

Mucosal telangiectases of the anterior gingival fold and hypertrichosis, diffuse or localised especially under the patella, are rare but suggestive features of juvenile DM. Cutaneous vasculopathy is also more prominent, leading to skin necrosis and subsequent ulcers. Dystrophic calcinosis affecting inflammatory skin and underlying muscles may cause extreme pain, deep ulcers and musculo-tendinous retractions with severe and persistent impotence. Localised lipodystrophy with loss of masseter and limb subcutaneous fat has been reported. Generalised lipodystrophy can also occur and is associated in 50% of cases with hirsutism, acanthosis nigricans, insulin-dependent diabetes and hypertriglyceridaemia.

2.6 DM, auto-antibodies and cancer

Skin necrosis, cutaneous leucocytoclastic vasculitis, vesiculo-bullous lesions in non-traumatised areas and pruritus or a burning skin sensation occurring in older patients are cutaneous signs strongly suggesting malignancy. A strong association with specific autoantibodies (anti-TIF1-gamma and anti-NXP2) is observed. Inversely, in childhood DM (despite the presence of anti-NXP2), adult DM with anti-Mi-2 or anti-MDA-5, mixed

connective tissue diseases (anti-RNP, anti-PM-Scl, anti-Ku) and anti-synthetase syndrome (anti-Jo1 and other anti-synthetase), the risk of associated malignancy is extremely low; those patients have however a higher risk of potentially life-threatening interstitial lung disease

Breast, colon and lung carcinomas have been reported to be the most frequent tumours in DM; ovarian carcinoma has also been found much more frequently in women with DM than in the general population.

2.7 DM and other autoimmune diseases

It is important to look for dermatological signs of other connective tissue diseases in patients with DM because of the frequency of overlap syndromes. Mixed autoimmune diseases represent 10–20% of all inflammatory myositis, being more frequent in polymyositis (where skin is not affected) than in DM. The most common cutaneous findings are signs of overlap with scleroderma, especially CREST features (calcinosis, Raynaud's phenomenon, oesophageal dysmotility, sclerodactyly, telangiectasias), annular lesions suggestive of SCLE, and nodules suggestive of rheumatoid arthritis (RA). Other associated diseases include Sjögren syndrome and autoimmune thyroiditis. Cutaneous small vessel vasculitis can occur as an associated illness, especially in patients with juvenile DM.

2.8 DM and drugs

Many drug categories are known to induce myositis (fibrates, statins, anti-retroviral molecules, interferon, isoniazide, tamoxifen, chlorpromazin, antazolin, clemizol, phenylbutazone, D-penicillamine,...). However, published reports of genuine drug-induced DM, especially with statins, are scarce and have a low level of evidence, except for DM induced by immunological checkpoint inhibitors such as ipilimumab (anti-CTLA-4). D-penicillamine might induce DM or polymyositis in patients with rheumatoid arthritis. Hydroxyurea can produce, in 5% of treated patients, streaks of erythema over the hands similar to DM lesions but without muscle involvement. Moreover, patients taking hydroxyurea tend to have late onset (2 months) of DM. DM-like skin manifestations have also been reported with the following drugs: etoposide, cyclophosphamide, diclofenac and acetylsalicylic acid. The majority of cases of drug-induced DM improve after withdrawal of the medication thought to play a role.

3 Skin manifestations in systemic scleroderma

Skin manifestations in systemic scleroderma (SSc) are very important and can lead to diagnosis at first sight (Gabielli et al, 2009*). The 2013 ACR-EULAR diagnostic and classification criteria for SSc (Van den Hoogen et al, 2013*) determined that skin thickening of the fingers extending proximal to the metacarpophalangeal joints is sufficient for the patient to be classified as having SSc. If that sign is absent, seven additive items are considered, with varying weights for each: skin thickening of the fingers, fingertip lesions, telangiectasia, abnormal nailfold capillaries, interstitial lung disease or pulmonary arterial hypertension, Raynaud's

phenomenon and SSc-related autoantibodies. These criteria replace the previous criteria of LeRoy et al which emphasised the distinction between limited cutaneous scleroderma and diffuse cutaneous scleroderma. In limited cutaneous scleroderma (lcSSc), fibrosis is restricted to the hands, lower arms, neck and face. Raynaud's phenomenon is present for several years before fibrosis appears, pulmonary hypertension is notably frequent, and anticentromere antibodies occur in 50–90% of patients. Diffuse cutaneous scleroderma (dcSSc) is the more rapidly progressing subtype that affects larger areas of the skin and compromises one or several internal organs (pulmonary fibrosis as well as heart and kidney involvement).

In rare cases, patients with SSc have no obvious skin involvement. Patients with scleroderma and additional clinical signs of SLE, RA, polymyositis/dermatomyositis or Sjögren's syndrome are considered to have an overlap syndrome.

3.1 Vascular skin changes

Almost all patients have Raynaud's phenomenon, which generally precedes other manifestations. It is characterised by episodic vasospastic attacks that cause the blood vessels in the fingers and toes to constrict. It presents with three changes in skin colour. Pallor (in response to arteriole spasm) is followed by cyanosis (due to ischaemia) and then rubor (after arteriole reperfusion and dilation). Raynaud's phenomenon affects the fingers, toes, ears and nose. The duration of an attack varies from a minute to several hours/days. As the attack ends, finger and toe tips may throb and tingle.

Recurrent Raynaud's phenomenon is thought to be the direct consequence of structural changes in the vessels and perturbed control of vascular tone due to an imbalance between vasodilatory and vasoconstrictive mediators.

Unlike in rosacea, telangiectases in scleroderma are rounded or rectangular and affect not only the face, but also the trunk, the palms (figure 29) and the oral mucosa. They can be distinguished from Rendu-Osler disease lesions because the latter are papulous and not flat; moreover, bleeding never occurs. Facial abnormal telangiectases are one of the characteristic CREST signs. The term 'CREST syndrome' is becoming obsolete as it is not exclusive to a single subgroup of patients with the disease and does not sufficiently indicate the burden of internal organ involvement. Most patients with CREST syndrome are females with a long history of secondary Raynaud's syndrome before acroscleroderma develops. The prognosis of these patients is favourable if pulmonary hypertension does not occur. However, some scleroderma patients, frequently males, show disseminated telangiectases over the chest and trunk and develop severe lung disease and other organ manifestations associated with a poor outcome. Serologically, these patients are characterised by scleroderma-specific anti-nucleolar antibodies.

Figure 29 *Telangiectases on the skin of the hand.*

3.2 Fibrotic skin changes

Skin sclerosis first starts at the extremities (acroscleroderma), especially around the fingers and toes, which become initially oedematous with a characteristic puffy appearance, as in mixed connective tissue disease (Sharp's syndrome). Pads become smooth and lose fingerprints. Next, the skin becomes shiny and tight, binding to deeper structures mainly on the dorsum of phalanges. Movements are progressively limited, the joints are fixed in flexion, and fingers have a tapered appearance with difficulty obtaining full extension (sclerodactyly) (figure 30). Changes may extend proximally to involve the forearms and upper arms and can result in dermatogenic joint contractures, especially of the elbows and knees. Dermal sclerosis also leads to atrophy of appendages and subsequent decreased sweating and hair loss.

Figure 30 *Sclerodactyly.*

The face is frequently involved (figure 31). Sclerosis produces an abnormal tense feeling with an amimic facies. Forehead wrinkles disappear. Eyelids become retracted giving a particular look. The nose becomes small and pinched. The lips become thinner, and protrusion of the tongue is difficult. The mouth opening is constricted (microstomia), impairing proper dental hygiene, and marked radial peribuccal furrows appear. Resurfacing laser on the peri-oral skin is under evaluation. Filling with inert substances (collagen, proteoglycans and silicone) is not recommended.

Figure 31 Patient with systemic scleroderma with disappearance of forehead wrinkles, a tapered nose and perioral wrinkles. (Patient consent obtained.)

On the scalp, skin binds to the bone and alopecia may occur.

Oral mucosa can be affected with characteristic shortening of the tongue frenulum and widening of the periodontal membrane due to sclerosis, especially of the incisive alveolodental ligament. Bare teeth may follow gingival retraction. The mucosa is pale and dry.

The skin is tight, shiny, bound down, hard, and impairs breathing, and abdominal and joint movements.

3.2.1 Histological features

The diagnosis of skin sclerosis is clinical. Histology shows non-specific features that are similarly found in morphea. In the initial phase, deep dermis presents with an inflammatory infiltrate; lymphocytes, plasma cells and some mast cells accumulate around vessels and between homogenised collagen bundles dissociated by oedema. At a later stage, epidermal atrophy may occur with loss of the rete ridges. The dermis is markedly thickened with dense bundles of collagen. The elastic tissue is reduced and elastic fibres are horizontally flattened. Dermal appendages and vessels are progressively lost.

3.3 Other skin manifestations

Fingers commonly show micro-ulcerations of the pads or the dorsum of the joints, pitted scars (figure 32), digital gangrene, and dystrophic slow-growing nails curving over atrophic phalanges; distal nail bed adherence

to the ventral surface of the nail plate (pterygium inversus unguis) is typical. Dilated capillaries and micro-thrombotic changes in the nail fold are similar to those observed in DM and can be verified by capillary microscopy (figure 33).

Figure 32 Ulcerations and pitted scars.

Figure 33 Megacapillaries on capillaroscopy.

Painful digital ulcers sometimes involving all fingertips are a major problem for scleroderma patients and greatly reduce their capacity to cope with the disease. They occur mostly in patients with diffuse skin involvement and multiple organ involvement, especially lung fibrosis and/or pulmonary arterial hypertension. Local dressings and systemic vasodilators (prostacyclin derivatives) are the mainstay of ulcer treatment. Bosentan, an endothelin receptor antagonist, has a proven but weak preventive effect on digital ulceration (30 to 50% reduction) without effect on ulcer healing. Preliminary studies suggested that the 5-phosphodiesterase inhibitor, sildenafil, may induce healing of digital ulcers in scleroderma patients, but a placebo-controlled study failed to confirm these results. These digital ulcerations need a multi-disciplinary approach with the prescription of different vasodilators (prostacyclin derivatives, bosentan, sildenafil, calcium channel blockers, ACE inhibitors and others) and physiotherapy.

Calcium deposits accumulate insidiously in the skin forming nodules that are mobile in relation to deep structures but tightly bound to overlying skin, giving a whitish appearance. They can be found on the hands (figure 34), forearms, wrists, elbows, shoulders and knees (figure 35). Nodules can grow considerably and resemble tumours. Complications include painful inflammatory flare, pseudo-dactylitis, and ulceration with discharge of chalky material. Large nodules are visible on soft tissue radiography.

Figure 34 Calcium deposits in scleroderma.**Figure 35 Calcific plaque in scleroderma.**

Pigmentary changes are frequent, especially on sclerotic skin. Diffuse hyperpigmentation associated with severe pruritus can be seen in rapidly progressive dcSSc with a poor prognosis. Diffuse or mottled hyperpigmentation may affect white skin, whereas peri-follicular hypo-pigmentation is commonly seen on dark skin (figure 36). On white skin, depigmentation with a relative sparing of the perifollicular areas is typical (“salt-and-pepper” appearance). Pruritus may be severe in early active scSSc and notably challenging to alleviate.

Figure 36 Depigmentation in scleroderma.

3.4 Laboratory investigations

Anti-centromere antibodies are more frequent in localised (65%) than in diffuse cutaneous SSc (30%), whereas anti-DNA topoisomerase I (anti-Scl 70) antibodies are more frequent in diffuse (40%) than in limited forms (20%). Other scleroderma-specific antibodies, found mostly in patients with overlap syndromes or with diffuse SSc and severe organ involvement, are frequently directed against nucleolar antigens such as fibrillarin.

3.5 Scleroderma and drugs

Systemic sclerosis-like syndrome may be induced by various drugs including bleomycin, taxane, pemetrexed, tryptophan, and rarely fosinopril. In drug-induced systemic sclerosis-like syndrome, ANA can be sometimes detected but usually there are no SS-specific antibodies. The characteristics of bleomycin-induced scleroderma are male predominance, a high incidence of limited-type cutaneous sclerosis and a low incidence of Raynaud's phenomenon, digital pitting scars, ANA and visceral involvement compared with idiopathic SS. Sclerosis and swelling of the hands and forearms usually resolve after the termination of bleomycin-containing chemotherapy, but sclerodactyly can persist in some cases. Bleomycin also has dose-related pulmonary toxicity that manifests as interstitial pneumonia and pulmonary fibrosis. Taxane-induced scleroderma is a clinical condition presenting with localised oedema evolving into skin sclerosis. Differently from classic SSc, taxane-induced scleroderma did not display the characteristic symptoms associated with SSc, such as Raynaud's phenomenon, nail fold changes, and pulmonary fibrosis. In SSc, skin sclerosis usually begins on the fingers and advances towards the centre of the body in a symmetrical pattern, whereas in most patients with taxane-induced scleroderma, lesions first arise on the legs. Scleroderma can develop during taxane chemotherapy or within 2 years after the termination of chemotherapy. L-tryptophan has also been reported to cause skin induration associated with myalgia and eosinophilia, but was banned by the US Food and Drug Administration in 1989.

4 Skin manifestations in systemic vasculitis

Skin manifestations are frequently observed in almost all types of systemic vasculitis (Fiorentino, 2003*). Some correspond to skin localisation of the systemic vasculitis, while others result from a different pathological process. As a biopsy of a dermatological lesion is easy to obtain, it is useful and important for confirming the diagnosis (Carlson et al, 2005*); however, it may not be of value in determining the particular type of vasculitis as clinical and pathological features of the skin are not specific to a given type. Indeed, medium- and large-sized vessels are not present in the skin.

4.1 Skin manifestations of vasculitis

4.1.1 Clinical features

Skin vasculitis presents as a spectrum of clinical lesions including erythema, purpura, papules, pustules, nodules, livedo, necrosis, ulcerations and bullae. These various lesions often co-occur giving the eruption a pleomorphic appearance.

Palpable purpura is unquestionably the most frequent manifestation (figure 37). Lesions usually begin as tiny red macules that later become papules and plaques ranging from several millimetres to several centimetres in width. Larger lesions are ecchymotic. The colour may change from red to purple to brownish-yellow as extravasated blood is progressively broken down. Palpable purpura is most common on the legs, ankles and feet, but other areas of the body can be affected.

Figure 37 Palpable purpura.

Urticarial vasculitis (also called anti c1q vasculitis) (figure 38) is characterised by *wheals* that persist for 2–3 days, unlike ordinary urticaria which is expected to clear within 24 h. Pruritus is less intense than in common urticaria. Lesions may become purpuric. They are mainly located on the trunk and the limbs. Elsewhere, other papules, which are not purpuric or urticarial, may also correspond to skin vasculitis, especially when found on the outer aspects of the limbs. Some papules appear red to purple, then become brown to yellow and follow a chronic evolution as in erythema elevatum diutinum (EED).

Figure 38 Urticarial vasculitis.

Pustular vasculitis (figure 39) is usually non-follicular, with underlying erythema. Other frequently observed pustules may result from secondary infection of necrotic lesions.

Figure 39 Pustular vasculitis.

Nodules in vasculitis are typically inflammatory, tender, red and small (figure 40). They are mainly located on the lower limbs (legs, soles), where they can be surrounded by livedo reticularis/racemosa, but are also observed on other sites such as the dorsal aspect of the upper limbs or, rarely, the trunk. Nodules may also occur in groups along the course of superficial arteries.

Figure 40 Nodular vasculitis.

Livedo racemosa is a reddish-blue mottling of the skin in a 'fishnet' reticular pattern (figure 41). It is typically irregular with broken meshes. Some infiltrated areas are found on careful examination. When associated with vasculitis, livedo persists indefinitely with some fluctuations in intensity and extent as temperature varies.

Figure 41 Livedo in vasculitis.

Necrosis (figure 42) results from the obstruction of dermal vessels. Its extent and depth are highly variable depending on the extent and depth of the involved vessels. Localised necrotic lesions may develop into vesicles. Pustules may appear due to secondary infection. When necrosis is extensive, painful purpura is followed by a black necrotic plaque with an active purpuric border and bullous lesions. After removal of necrotic tissue, ulcers of various sizes develop.

4.1.2 Histopathology and clinico-pathological correlation

Leucocytoclastic vasculitis of the superficial dermal vessels is the pathological hallmark of palpable purpuric lesions. Post-capillary venules are preferentially involved. Leucocytoclastic vasculitis is characterised by vascular alterations and dermal cellular infiltrates.

Vascular alterations consist of endothelial cell swelling, necrosis with deposition of fibrinoid material into the vessel wall, and sometimes thrombosis. The fibrinoid material is predominantly made of fibrin but contains

also necrotic endothelial cells and deposits of immuno-reactants (immunoglobulins and/or complement proteins).

Dermal infiltrates vary in intensity. They are usually peri-vascular but at times widely dispersed. Neutrophils are the main cells and often the nucleus fragments (karyorrhexis or leucocytoclasia). In other cases or at a later stage, lymphocytes and monocytes may predominate.

In some patients, especially those with immune complex-mediated vasculitis and extensive complement activation, dermal small-vessel vasculitis generates focal dermal oedema with subsequent urticaria.

Nodular lesions of vasculitis results from inflammation of vessel walls at the dermo-hypodermal junction or in the subcutaneous fat. When arterioles are involved, pathological features are similar to those observed in cutaneous polyarteritis nodosa (PAN). Endothelial swelling and fibrinoid necrosis of the media are often severe with variable thrombosis. Invasion of the vessel wall with neutrophils usually occurs in the acute phase, although leucocytoclasia is less frequently observed. In other cases, the infiltrate can be initially granulomatous. In the healing phase, the vessel wall is invaded by granulation tissue and replaced by a fibrous scar. Continuous proliferation of capillaries occurs.

In summary, palpable purpura and papular lesions such as urticaria indicate a leucocytoclastic or lymphocytic vasculitis of the small vessels of the dermis. Nodules indicate a vasculitis of arterioles or vessels at the dermo-hypodermal junction or in the subcutaneous fat. Necrosis and livedo occur when either small and/or larger vessels are involved.

Figure 42 Necrosis in vasculitis.

4.1.3 Other skin manifestations associated with systemic vasculitis

4.1.3.1 Extravascular necrotising granuloma

Initially described by Churg and Strauss in 1951 as a manifestation of eosinophilic granulomatosis with polyangiitis (EGPA, formerly called allergic angiitis or Churg–Strauss syndrome), extravascular granuloma has also been described in many other types of systemic vasculitis and connective tissue diseases. Papular or nodular lesions vary in size from 2 mm to 2 cm or more, and in colour from red to purple. Central umbilication, crusting and/or ulceration are frequent. Rarely, other features are reported such as vesicles, pustules, arciform plaques or firm masses. Sites of involvement are the extensor aspects of the elbows, the fingers where there are usually multiple lesions (often symmetrical), and less frequently, the buttocks, scalp, knees, hands, dorsum of the feet, neck, forehead and ears.

Histological features include endothelial necrosis and oedema, fibrinoid necrosis of the collagen, and granulomas containing eosinophils, histiocytes and lymphocytes. The centre of the granuloma consists of basophilic (rather GPA) or eosinophilic (rather EGPA) fibrillar necrosis in which bands (sometimes linear) of destroyed tissue are interspersed with poly-morpho-nuclear leucocytes and leucocytoclastic debris. This necrotic area is surrounded by a granulomatous mass of histiocytes, often in a palisade array. A decrease in or absence of elastic fibres is observed in foci of degenerated collagen. No relationship is seen between the clinical appearance of lesions, the histological features, and the associated systemic disease. However, tissue eosinophilia is more frequently reported in patients with EGPA.

4.1.3.2 Panniculitis

Cutaneous eruption consists of recurrent crops of erythematous, oedematous and tender subcutaneous nodules or of a deep poorly limited infiltration. The nodules are 1–2 cm in diameter but may be much larger. Histologically, panniculitis is characterised by an inflammatory infiltrate composed of lymphocytes, plasma cells and histiocytes in adipose tissue. They can be classified as lobular or septal depending on whether the inflammatory infiltrate is more abundant in the lobules, the interlobular septa or around the vessels of the subcutaneous tissue septa. In lobular panniculitis, lesions are usually symmetrically distributed on the thighs and the posterior part of the lower legs. They usually regress spontaneously, leaving hypopigmented and atrophic scars due to fat necrosis. Occasionally, they may suppurate. In septal panniculitis (erythema nodosum), nodular lesions are primarily located over the anterior aspects of the lower limbs. They regress spontaneously without atrophic scarring and do not suppurate.

4.1.3.3 Pyoderma gangrenosum

Pyoderma gangrenosum (PG) lesions usually begin as deep-seated, painful nodules or as superficial haemorrhagic pustules, either de novo or after minimal trauma. They further break down and ulcerate,

discharging purulent and haemorrhagic exudates (figure 43). Ulcers can reach 10 cm or more in diameter, partially regress or remain indolent for a long period. The irregular edges are raised, red or purplish, undermined, soggy and often perforated. The most commonly affected sites are the lower extremities, buttocks and abdomen, but other areas of the body may be involved. Lesions are usually solitary but may arise in clusters, which then coalesce to form polycyclic irregular ulcerations. When healing occurs, an atrophic and often cribriform scar is left. PG lesions can be found alone or in association with a systemic disease (inflammatory bowel disease, rheumatoid arthritis, haematological disorder) or a systemic vasculitis, namely granulomatosis with polyangiitis (GPA), Takayasu arteritis or Behçet's disease. Infectious pyodermitis must always be ruled; substantial pain is a distinguishing feature.

Figure 43 *Pyoderma gangrenosum*.

The histological features, when a biopsy is performed, consist of a large, sterile abscess in which thrombosis of small and medium blood vessels, haemorrhage and necrosis are present. Neutrophils are numerous, but epithelioid, giant and mononuclear cells are also seen, especially in the more chronic forms. Leucocytoclastic or lymphocytic vasculitis may be observed, particularly in the active border of the lesion. These changes are not specific and may be observed within the main differential diagnosis, i.e. infectious ulcerations; besides pathergy is frequently observed with secondary exacerbation of the disease around the biopsy site. The diagnosis is therefore essentially based on clinical findings and negativity of microbiological swabs.

4.1.3.4 Granuloma

Granulomatous lesions without vasculitis or central necrosis may be observed in systemic vasculitis, especially granulomatous with polyangiitis (GPA, formerly Wegener's granulomatosis). The clinical aspect is highly variable, ranging from papules, nodules, subcutaneous infiltration and pseudo-tumour to chronic ulcers. Any site of the body may be involved: the breasts, scrotum, face, gums, etc. Other granulomatous diseases have to be considered in the differential diagnosis, such as sarcoidosis, metastatic Crohn's disease, mycobacterial infections, and foreign body granulomas.

4.1.3.5 Superficial thrombophlebitis

Thrombophlebitis of a superficial vein is sometimes clinically evident due to the presence of painful induration of the vein with redness and increased heat. In other cases, the clinical aspect is a linear or even non-specific red nodule and diagnosis is only confirmed by histological examination of a deep skin biopsy; ecodoppler investigations do not allow diagnosing nodular thrombophlebitis in most cases. Such lesions are essentially observed in thromboangiitis obliterans, Behçet's disease, Crohn's disease and relapsing polychondritis, but may also be observed in the context of an underlying malignancy (migratory thrombophlebitis, or Trousseau's syndrome).

4.1.3.6 Gangrene

Gangrene resulting from arterial occlusion may be observed in all types of vasculitis involving medium or large arteries. It is initially characterised by a sharply demarcated blue-black colour of the extremities. The main differential diagnoses are thrombosis, without inflammation of the vessel walls, and emboli. Angiography visualises occlusion or stenosis of arteries but does not help to differentiate these different pathological processes. The presence of other skin lesions with histologically proven vasculitis suggests vasculitis, although thrombosis, vasculitis and emboli may be concomitant as in atheromatous emboli.

4.1.3.7 Raynaud's phenomenon

Bilateral Raynaud's phenomenon may occur in 5–30% of a randomly selected population. It is classically associated with all types of vasculitis. However, its prevalence is unknown in many vasculitides and its diagnostic value is very low. In contrast, unilateral Raynaud's phenomenon suggests an obstructive arterial disease and, within the spectrum of vasculitides, is mainly observed in Takayasu's arteritis.

4.1.3.8 Interstitial granulomatous dermatitis

Interstitial granulomatous dermatitis (IGD) is an entity first described by AB Ackerman, and characterized histopathologically by a granulomatous inflammatory infiltrate centred on collagen bundles, with symmetrical, erythematous cords or plaques, mainly involving the lateral chest wall, abdomen and medial thighs clinically (figure 44). Other clinical findings present in 10% of patients include typical erythematous, asymptomatic, linear, palpable cord-like lesions on the lateral aspects of the trunk (the rope sign) (figure 45) and urticarial plaques. It is an uncommon disorder.

Figure 44 Plaques in interstitial granulomatous dermatitis.

Figure 45 The rope sign in interstitial granulomatous dermatitis.

Histopathologically, IGD is quite distinct and characterised by a dense, diffuse dermal inflammatory infiltrate composed primarily of histiocytes distributed interstitially and in a palisaded array. In the deep reticular dermis, small foci of degenerated collagen are enveloped by large numbers of neutrophils and/or eosinophils; this latter finding is the most characteristic.

IGD may be associated with various autoimmune vascular diseases (including RA, SLE, Still's disease, EGPA, thyroiditis and vitiligo), infections and drug intake. Although its cause remains unknown, its association with these conditions makes an immune complex-mediated pathogenesis likely.

4.2 Dermatological findings in the main systemic vasculitides (table 3)

Table 3 Skin signs in systemic vasculitis

Systemic vasculitis	Most frequent skin lesion	Most typical skin lesion
IgA vasculitis	Purpura, urticaria	Purpura, urticaria
Cryoglobulinaemic vasculitis	Purpura	Purpura with secondary pigmentation
Polyarteritis nodosa	Purpura	Nodules, livedo
Microscopic polyangiitis	Purpura, nodules	Purpura
Eosinophilic granulomatosis with polyangiitis	Purpura	Extravascular necrotising granuloma
Granulomatosis with polyangiitis	Purpura	Oral ulcers, gingival hyperplasia

4.2.1 IgA vasculitis

Purpuric lesions associated with arthritis, gastrointestinal symptoms and IgA nephritis are considered a distinct entity among the different types of angiitis and are called IgA vasculitis (figure 46). In the past, this entity was known as Henoch-Schönlein purpura, anaphylactoid purpura, allergic purpura and haemorrhagic capillary toxicosis. This type of vasculitis predominantly occurs in children, where it represents more than 90% of all types of vasculitis, although all ages can be affected. There is no seasonal pattern, but a higher incidence in winter and a lower incidence in summer have been recorded, probably in relation to infections that are possible triggers. This purpura is caused by deposition of immune complexes in the small vessels, and immune complex formation is induced by bacterial (*Streptococcus*, *Mycoplasma pneumonia*, etc.) or viral (Epstein-Barr virus, cytomegalovirus, etc.) infections, vaccines or drugs (penicillin, aspirin, etc.).

Figure 46 IgA vasculitis.

Some 70% of patients exhibit gastrointestinal discomfort or joint pain, especially of the large joints, and 40% of patients have glomerulonephritis with IgA deposition.

Skin lesions begin as a crop of red macules, some of which resolve in the early stage while others become papular, urticarial or purpuric. In some cases, the characteristic urticarial component of the rash is missing and purpura is the only sign. When inflammation and exudation are severe with involvement of all superficial vessels, haemorrhagic vesicles, bulla, necrosis and ulcers develop. The most common sites are the extensor aspects of the limbs, the buttocks, the back, and occasionally the face (peri-ocular haemorrhagic oedema). Rarely, oral mucosa is involved. Lesions occur in successive waves and then resolve spontaneously.

Infantile acute haemorrhagic oedema is considered by some to be a distinct clinical entity, especially because it has a better prognosis, but is thought by others to be a variant of IgA vasculitis. It is characterised by the following features: febrile onset in children below 2 years of age; oedema of the scalp, hands, feet and peri-orbital tissue preceding purpura; and lack of renal and gastrointestinal involvement. Recovery is expected within 3 weeks.

Oedema probably results from increased capillary permeability due to an underlying vasculitis.

On histology, early changes are essentially those of leucocytoclastic vasculitis with endothelial swelling, fibrinoid necrosis and extravasation of erythrocytes. In the later stages, mononuclear cells may predominate. The superficial dermal vessels are exclusively involved. The frequency of dermal IgA vessel deposits varies depending on the series. These IgA deposits are sometimes included in the diagnostic criteria of dermatology series and thus are present in 100% of cases. Inversely, these deposits are present in only 50% of patients of nephrology series where IgA nephropathy is present in 100% of cases. These dermal IgA deposits are not specific for IgA vasculitis; they may be encountered in many cutaneous vasculitides.

4.2.2 Cryoglobulinaemic vasculitis

Cryoglobulinaemia may be idiopathic or secondary to other systemic diseases such as infections, cancer or autoimmune disorders. The pathogenesis of this vasculitis is mediated by immune complexes formed by cryoglobulins, antibodies that precipitate at low temperatures. Only monoclonal antibodies are found in type I cryoglobulinaemia, monoclonal and polyclonal antibodies are found in type II, and polyclonal antibodies of different classes are found in type III. Type II and III are called 'mixed' cryoglobulinaemia.

As HCV infection is the main aetiology of mixed cryoglobulinaemia (especially type II), the influence of this infection on clinical presentation has been studied. Globally, the clinical and histological aspects of purpura are similar whether HCV infection is present or not.

Skin manifestations occur in 60–100% of patients with symptomatic cryoglobulinaemia. They are a frequent presenting complaint and often accompany arthralgia and fatigue. Renal and hepatic involvement is also frequent. The disease tends to wax and wane. Women outnumber men with a female:male sex ratio of 1.3:1. The average age of onset is 50 years. The interval between the first skin manifestation and diagnosis of

cryoglobulinaemia varies from 0 to 10 years. Palpable purpura of the lower extremities is the main manifestation, present in 92% of patients. Sometimes, purpuric lesions are masked by secondary diffuse pigmentation mimicking chronic venous insufficiency changes. Lesions are more commonly observed on the head and mucosal areas (ears, nose and mouth) in type I cryoglobulinaemia. Seasonal triggering of flares is frequently reported. Raynaud's phenomenon, acrocyanosis, livedo and cold urticaria are other possible manifestations during cold seasons. Post-inflammatory pigmentation is noted in 40% of patients and can retrospectively evoke the diagnosis. Infarction, haemorrhagic crusts and ulcers are present in 10–25% of patients. Widespread necrotic areas are relatively more common in type I cryoglobulinaemia.

Involvement of the skin is due to two major mechanisms: leukocytoclastic vasculitis (related to immune complex deposit) in type 2 cryoglobulinemia and/or occlusion of cutaneous vessels by precipitation of cryoglobulins in cold-exposed areas in type 1 cryoglobulinemia. Histology shows a leukocytoclastic vasculitis and rarely characteristic PAS-positive material in the vessel lumen, corresponding to the cryoprecipitate. Direct immunofluorescence studies have shown IgM, IgG and C3 deposits in some patients with acute vasculitis. In type I cryoglobulinaemia, thrombosis is the main histological feature, while signs of true vasculitis are usually lacking.

4.2.3 Polyarteritis nodosa

According to the names and definitions of vasculitis adopted by the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis, classic PAN is characterised by necrotising inflammation of medium-sized muscular arteries without glomerulonephritis or vasculitis in arterioles, capillaries or venules and it is not associated with anti-neutrophil cytoplasm antibodies (ANCA's).

The aetiology is unknown in most cases, while pathogenesis seems to be mediated by immune complexes. The triggering antigen could derive from viral infections such as hepatitis B or C.

Systemic PAN is very rare; its evolution is acute with skin manifestations different from those observed in cutaneous PAN. Skin lesions occur in 15–60% of patients with systemic PAN and are less frequently observed in patients above 65 years of age. Although this systemic disease mainly affects the medium arteries of the kidney, liver, heart and gastrointestinal tract, the most common cutaneous finding is palpable purpura corresponding to a small vessel vasculitis (which, *per definition*, should not occur, as it is the consequence of small vessel involvement). Nodules (8–27%), ulcerations and livedo of the racemosa type are less frequent. Other manifestations have been reported such as urticaria, transient erythema, superficial phlebitis, Raynaud's phenomenon, splinter haemorrhages and digital infarction.

The skin hallmarks of cutaneous PAN are nodules (Diaz-Perez et al, 2007*). These cutaneous or subcutaneous nodules appear in groups along the course of superficial arteries. They measure between 5 and 15 mm in

diameter and are mainly located on the lower legs, especially around the knees and on the feet. Livedo may precede, accompany or follow the onset of nodules. In *cutaneous PAN*, livedo of the racemosa type is typically located on the lower limbs, the dorsal aspects of the upper limbs, and rarely the trunk. The fishnet reticular pattern is irregular with broken meshes. On careful examination, some tender infiltrated areas are found. Painful ulcerations are frequently associated with tender and firm plaques resulting from coalescent nodules. These clinical features are characteristic of cutaneous PAN, which, by definition, only affects small arteries and arterioles of the skin and adjacent skeletal muscle, joints and peripheral nerves with consequent myalgia, arthralgia and pure sensitive neuropathy (mononeuritis multiplex). Cutaneous PAN is more chronic than systemic PAN and does not usually evolve into systemic PAN.

4.2.4 Microscopic polyangiitis

The microscopic form of PAN, now called microscopic polyangiitis (MPA), is defined as a systemic vasculitis of small blood vessels (i.e., capillaries, venules or arterioles) without granuloma. MPA is associated with segmental necrotising rapidly progressive glomerulonephritis and ANCA mainly of the myeloperoxidase type.

Dermatological manifestations occur in 30–58% of patients. Palpable purpura of the lower limbs is the most frequent. Other lesions have been reported such as mouth ulcers, vesicles, necrosis, ulcerations, nodules, splinter haemorrhages, livedo, urticaria and facial oedema. All these skin lesions rapidly disappear with treatment.

4.2.5 Eosinophilic granulomatosis with polyangiitis (EGPA)

In 1951, Churg and Strauss defined allergic granulomatosis as a distinct entity occurring in adults with asthma and associated with fever, eosinophilia, systemic vasculitis and extra-vascular granulomas (figure 47). Churg–Strauss syndrome is now known as eosinophilic granulomatosis with polyangiitis (EGPA).

Figure 47 Churg–Strauss granulomas.

The aetiology is unknown although some clinical (allergic respiratory disease) and biochemical (hypereosinophilia and sometimes total IgE elevation) features suggest that infectious or allergic factors such as *Aspergillus* can induce immune-complex or cell mediated reactions.

Usually the disease starts with allergic rhinitis, followed by asthma, hypereosinophilia, and chronic pneumonia or eosinophilic gastroenteritis. Skin lesions have been observed in 40–70% of cases depending on the series. They are rarely inaugural (6%). Palpable purpura on the lower extremities is the most frequent skin sign and is often necrotic. Cutaneous nodules or papules are also very frequent, and located on the lower limbs or on the extensor side of the elbows, fingers, scalp and breast. Lesions of the fingers are usually multiple, often symmetrical, and most commonly localised on both lateral sides of the distal interphalangeal joint. These nodules or papules of the upper limbs frequently have central crusting or ulceration. Their consistence is usually firm. A pustular or vesicular component is rarely noted. Various other dermatological lesions have been reported: maculo-papules resembling erythema multiforme, ulcerations, livedo reticularis, urticarial rash, nail fold infarction with splinter haemorrhages, and facial oedema.

The histological findings of skin lesions can be disappointing, typical granuloma and eosinophils being detected in less than half of patients. ANCA are present in almost half of patients and are usually p-ANCA. Skin lesions rapidly respond to systemic glucocorticoids, but additional immunosuppressive medications are often used to control the systemic disease.

4.2.6 Granulomatosis with polyangiitis (GPA)

Granulomatosis with polyangiitis (GPA), formerly known as Wegener's granulomatosis, is characterised by involvement of the upper airway, lungs and kidneys, although all organs can be affected. Its pathogenesis mostly depends on the activation of cell mediated immunity, responsible for the formation of granulomas, and on c-ANCA production. Skin lesions occur in 14–77% of cases depending on the series. They are inaugural in about 10% of cases and are rarely isolated. Palpable purpura of the lower extremities is the most frequently observed lesion. Necrotic papules of the extensor aspects of the limbs are less frequent, but more suggestive of GPA. Exceptionally, skin features are similar to those in EED with IgA paraproteinaemia. Nodules are quite frequent, and mainly localised on the limbs. Extensive and painful cutaneous ulcerations may precede other systemic manifestations by weeks to years. These ulcers are sometimes described as 'PG-like lesions', especially when they follow localised trauma or the breakdown of painful nodules or pustules. However, they usually lack the typical raised, tender, undermined border of PG. Sometimes numerous, they are located on the limbs, trunk, face (pre-auricular area), breasts (mimicking adeno-carcinoma with possible nipple retraction and galactorrhoea) and perineum. Digital gangrene is occasionally reported. Florid xanthelasma is associated with long-standing granulomatous orbital and peri-orbital infiltration. In contrast to PAN, livedo reticularis is unusual in GPA.

The frequency of oral manifestations is difficult to estimate from literature series since they are often included in ear-nose-throat symptoms and not described separately. Oral ulcers are sometimes reported independently of other oral manifestations. They are undoubtedly frequent, and present in 10–50% of cases depending on the series. Unlike aphthae, they are persistent and not recurrent. Their number and localisation are highly variable. Gingival changes include gingival hyperplasia with a granular aspect, red to purple colour and many petechiae (figure 48). The entire peri-odontium and gingival mucosa may be involved, resulting in tooth mobility and loss of teeth. Significant but incomplete improvement is observed with empiric antimicrobial therapy. Genital ulcers are uncommon, although penile necrosis has previously been described.

Figure 48 *Gingival hyperplasia in GPA (ex-Wegener's granulomatosis).*

Except for xanthelasma, all clinical and histological types of skin lesions are associated with active systemic disease. They disappear in few weeks or months after treatment onset. They are reported in about 50% of relapses. Skin lesions may be associated with joint and kidney involvement.

Since 1966, limited and sub-acute forms of GPA without kidney involvement have been identified. In our experience, the most frequently observed skin lesions in these forms are nodules with granulomatous infiltration or granulomatous vasculitis on histology.

4.2.7 Behçet's disease

In 1937, a Turkish dermatologist, Hulusi Behçet, described an entity consisting of oral aphthosis, genital aphthosis and ocular inflammation. Since then, various other manifestations have been related to this disease, which is known as Behçet's disease. Skin lesions are frequent and helpful for the diagnosis.

Complex aphthosis is the mucosal hallmark of this disease (Rashtak and Pittelkow, 2008*). Oral aphthae occur as the first manifestation in 25–75% of cases (figure 49). They are usually indistinguishable from ordinary aphthae. They form a 1–3 cm, painful ulceration of variable depth with a yellow fibrinous base surrounded by erythema. Patients may have single or multiples ulcers spontaneously healing in 1–4 weeks without scarring. Ulcers may also be herpetiform with pinpoint lesions occurring in coalescing clusters. The usually affected sites

are the lips, gums, cheeks and tongue, and, less frequently, the pharynx and palate. The frequency of recurrences is highly variable. In the diagnostic criteria of the International Study Group on Behçet's Disease, at least three recurrences per year are required. Pathological features are usually non-specific with rarely a lymphocytic or leucocytoclastic vasculitis. Genital aphthae are present in 60–80% of cases (figure 50). They are similar to oral aphthae but do not usually recur as often. In men, they are mainly localised on the scrotum with a permanent residual scar useful to the diagnosis, more rarely on the sheath or the meatus. In women, the vulva is predominantly involved. Ocular or perineal aphthae are rarely reported.

Figure 49 Aphthae in Behçet's disease.

Figure 50 Genital aphthae in Behçet's disease.

Pseudo-folliculitis is the most frequent skin lesion, observed in 39–60% of cases (figure 51). It presents as non-follicular erythematous, sometimes purpuric, papules that become sterile pustules, and then resolve or ulcerate. They are mainly located on the trunk, lower limbs, buttocks and genitalia but may occur on other parts of the body like the palms and soles.

Figure 51 Pseudofolliculitis in Behçet's disease.

On histology, there is an amicrobial neutrophilic infiltration with a lymphocytic infiltrate and a variable leucocytoclastic vasculitis. Non-bacterial folliculitis can be histologically indistinguishable from a bacterial folliculitis.

Nodules are present in 30–40% of cases, sometimes resembling erythema nodosum, on the anterior aspects of the lower limbs. Histology shows a septal or lobular infiltration of the hypodermis consisting of lymphocytes, histiocytes and neutrophils associated with septal vasculitis. Sometimes these nodules correspond to a superficial thrombophlebitis.

In a few patients, tender erythematous papules and plaques resembling those of Sweet's disease may be present on the face and neck. PG-like lesions have also been reported in some cases. The association with gastrointestinal involvement raises the difficult problem of the differential diagnosis with inflammatory enterocolitis. Other manifestations have been occasionally described: livedo reticularis, purpuric lesions, and erythema multiforme-like lesions.

The pathergy test is an induced cutaneous reaction resembling pseudo-folliculitis. When the skin is pricked by a needle or injected with saline, an erythematous papule or pustule develops within 24–48 h. Pathergy is a characteristic response in Turkish, Israeli, French and Japanese patients but is uncommon in North American and British patients. The use of needles with a large diameter and a blunt point seems to increase the sensitivity of this test. On histology, a lymphocytic and neutrophilic dermal infiltration has been observed in the first 24 h. Vasculitis is rare. Immunoglobulin and/or complement deposits in vessel walls may be obvious using direct immunofluorescence techniques.

4.2.8 Takayasu's arteritis

Takayasu's arteritis is a rare chronic inflammatory arteriopathy of unknown origin that predominantly affects the aorta, its main branches and the pulmonary arteries (Pascual-López et al, 2004*). Two, sometimes overlapping, stages of this disease have been distinguished: a first systemic inflammatory stage followed by an occlusive stage characterised by inflammation of the media and adventitial layers of large vessel walls resulting in vascular stenosis and/or aneurysm formation.

Skin manifestations have been reported in 2.8–28% of patients. Some are directly related to large vessel occlusion such as unilateral Raynaud's phenomenon, digital gangrene or unilateral digital clubbing.

Other skin manifestations frequently thought to be related to this vasculitis included ulcerated or non-ulcerated nodules of the lower limbs, PG, livedo reticularis, papular or papulo-necrotic lesions, superficial phlebitis and Sweet's lesions. Other manifestations which do not have an obvious relationship with Takayasu's arteritis include facial flushing, urticaria, angioedema, erythema multiforme and erythematous eruptions. The prevalence of these different skin lesions varies greatly from Asian to European countries.

In northern America and Europe, acute or subacute inflammatory nodules are the most commonly observed skin lesions. Erythema induratum corresponds to ulcerated subacute nodular lesions.

The histological features of these nodules are variable (granulomatous or necrotising vasculitis, extra-vascular granuloma, septal or lobular panniculitis). Usually, there is no correlation between the localisation of the nodules and large vessel alterations revealed by angiography. Furthermore, these nodules can occur at any stage of the disease. Tuberculoid infiltration has been reported in biopsies from papular or papulo-necrotic lesions, raising the suggestion of an infectious origin of the disease. These lesions mainly occur in the occlusive stage of the disease.

In Japan, PG-like lesions are frequent, especially in the occlusive stage; this type of lesions has also been reported in patients from northern Africa.

The relationship between skin manifestations and Takayasu's arteritis is based on the absence of other aetiology and on the parallel course of skin lesions and vasculitis. Whatever the stage of the disease, recurrence of skin lesions strongly suggests arteritis reactivation.

4.2.9 Giant cell arteritis

Giant cell arteritis (GCA) or Horton's arteritis is a systemic vasculitis with a predilection for cranial arteries in elderly patients. Skin manifestations are often observed in the late stages of the disease and so are actually rare due to early diagnosis.

Classically, the scalp and temples are tender and red, and tender nodules are palpable over the course of temporal, occipital or facial arteries. The pulse in these arteries is diminished or absent. Exceptionally, multiple scalp aneurysms have been reported.

The majority of other skin lesions are the consequence of ischaemia related to cranial artery occlusion and are localised on the tongue and scalp. Glossitis occurs in 10% of patients and may be revealing. The tongue has a red, raw-beef colour and may become blistered, scaling or gangrenous; necrosis usually occurs in the anterior two-thirds. Bullae, ulcers or massive necrosis may affect the scalp.

Patients with scalp necrosis constitute a subgroup of severe GCA with older age of onset and frequent serious complications such as visual loss, gangrene of the tongue or nasal septum necrosis. The mean interval between the onset of symptoms of GCA and scalp necrosis is 3 months. Under treatment, scalp healing is complete or satisfactory in 75% of cases. In other cases, skin grafts are possible. Less severe chronic ischaemia of the scalp leads to thinning or loss of hair. Ischaemic skin lesions of the neck or cheeks are occasionally reported. Rarely, vessels of the lower limbs are involved, leading to ischaemic ulcers or distal gangrene.

Skin biopsy of the border of ulceration or necrotic tissue is rarely helpful.

Senile purpura is frequent on sun-exposed skin in elderly patients, especially when treated with glucocorticoids. However, palpable purpura of the lower limbs due to this vasculitis is exceptional.

In conclusion, dermatological lesions are frequent in many systemic vasculitides. The most frequent cutaneous lesion is palpable purpura. It confirms vasculitis but does not determine its type. Histological examination of all other skin lesions is necessary. There is no correlation between the size of involved vessels and the type of peri-vascular infiltrate in the skin and other organs. Usually, in acute lesions the infiltrate is mostly composed of neutrophils, while lymphocytes are found in subacute lesions, and histiocytes and granulomas are predominant in chronic lesions.

5 Skin manifestations in rheumatoid arthritis

Extra-articular complications including dermatological manifestations occur in more aggressive and long-standing forms of RA.

The cutaneous conditions associated with RA can be divided into four groups: palisading granulomas, vascular and vasculitic lesions, neutrophilic dermatoses and miscellaneous disorders.

5.1 Palisading granulomas

5.1.1 Rheumatoid nodules

These skin changes develop in approximately 25% of patients with RA and represent the most common and most specific extra-articular manifestation of the disease. About 90% of patients with rheumatoid nodules are rheumatoid factor positive. The nodules generally develop as a later disease manifestation but may precede the joint involvement. The most frequently involved regions are areas with mechanically stressed skin such as over the olecranon, the hands (especially the fingers joints), the sacral prominences, Achilles' tendon and, less often, the ears and the head.

Rarely, rheumatoid nodules may be located in the tendons, synovium, bones, sclera, dura, and even the vocal cords and internal organs, particularly the lungs and the heart.

The size of these mostly indolent, hard, flesh-coloured, dome-shaped nodules varies from 5 to 15 mm; they may protrude above the skin or be palpable only subcutaneously or in soft areas (figure 52).

The characteristic histological features of rheumatoid nodules are dense deposits of eosinophilic fibrin surrounded by palisades of histiocytes, lymphocytes, plasma cells, and occasionally neutrophils and neutrophilic dust.

The majority of patients with rheumatoid nodules have severe forms of sero-positive RA, which may indicate a clinically poor prognosis. The nodules as such are mostly benign; only rare complications such as ulceration, infection, sepsis, and fistula formation require surgical intervention. Accelerated growth of rheumatoid nodules (rheumatoid nodulosis) can be observed in RA patients under treatment with methotrexate; besides rheumatoid nodules are more frequent in patients treated with leflunomide and TNF alpha blockers.

The differential diagnoses include pseudorheumatoid nodules (see section 5.1.2), subcutaneous granuloma annulare, Heberden's and Bouchard's nodules, fibrinoid nodules in skin borreliosis (acrodermatitis chronica atrophicans), tendon sheath xanthomas, gout tophi and foreign body reactions.

Figure 52 Rheumatoid nodules in a 72-year-old female patient.

5.1.2 Other cutaneous granulomas in RA (see also interstitial granulomatous dermatitis, chapter 4.1.3.8)

Pseudorheumatoid nodules are mostly seen in children but also in some adults without rheumatic disease. They mainly occur on the scalp and lower legs and are considered a deep, or juxta-articular form of granuloma annulare.

Palisaded neutrophilic granulomatous dermatitis (PNGD) is an uncommon skin manifestation in some patients with RA and has a variable clinical picture: initial lesions can be urticarial and later evolve to skin-coloured nodules. On the elbows, they may clinically resemble rheumatoid nodules. In other patients, cutaneous plaques or linear cords are seen, especially on the lateral aspects of the trunk (see section 4.1.3.8). The histological picture shows interstitial deposition of histiocytes, mucin and a peri-vascular infiltrate of neutrophils and plasma cells. Cutaneous mucinous nodules described mostly in Japanese patients with RA may represent another variant of PNGD clinically and pathologically characterised by extensive subcutaneous mucin deposition and proliferation of fibroblasts and of mononuclear cells.

5.2 Rheumatoid vasculitis

There is no universally accepted definition of rheumatoid vasculitis (RV). This rare condition should be considered in patients with RA when other disorders associated with secondary systemic vasculitis such as diabetes, cryoglobulinaemia, drug hypersensitivity and lymphoproliferative malignancies have been excluded. RV affects about 1–5% of patients with RA, mostly those with severe forms. The spectrum of clinical manifestations in RV is wide and ranges from minute digital petechiae, purpuric papules, or ulcers (Bywater's lesions) to widespread deep peripheral gangrene or PG-like ulceration.

Small to medium arterial or venous vessels are affected, most commonly those of the skin (80–90%) and the vasa nervorum of peripheral nerves (around 40%).

Other clinical manifestations of systemic vasculitis such as involvement of the central nervous system, the eyes and various internal organs are less frequent.

Peripheral nerve involvement typically manifests as distal, symmetric sensory and motor neuropathy and mononeuritis multiplex.

Focal digital purpuric papules, petechiae, leg ulcers and peripheral gangrene are the most common skin manifestations of RV. Cutaneous small-vessel vasculitis may sporadically occur in RA patients as a sign of drug hypersensitivity (see below); more typical are chronic vasculitic lesions resembling livedoid vasculitis or periarteritis nodosa with deep, often painful cutaneous ulcers (figure 53).

Figure 53 Rheumatoid vasculitis.

Whereas Bywater's lesions may occur without other signs of systemic vasculitis, leg ulcers or gangrene mostly represent complications associated with severe organ involvement and a poor prognosis.

Erythema elevatum diutinum (EED), a chronic form of leucocytoclastic small-vessel vasculitis characterised by mostly symmetric erythematous or yellow-brown plaques and nodules over the extensor surfaces of the extremities, represents a rare cutaneous manifestation of RV, but may also be seen in non-rheumatic individuals.

5.3 Neutrophilic dermatoses

5.3.1 *Pyoderma gangrenosum*

PG is the most severe of this heterogeneous group of inflammatory neutrophilic skin diseases; it can occur in about 10% of patients with RA, more often in women, but is also seen in association with other chronic inflammatory and autoimmune disorders such as Crohn's disease or with hematologic malignancies, or presents as an idiopathic disorder without apparent underlying disease.

PG (see section 4.1.3.3) starts with single or multiple small bullous lesions or pustules, mostly on the legs, or in the abdominal or genital-anal area; however, PG can occur elsewhere including on mucous membranes. The initial lesions may coalesce and rapidly progress to mature into ulcerative superficial granulomas and large necrotic and painful ulcers with a purulent base and characteristic reddish-blue undermined borders that extend centrifugally (figure 54). Single lesions can be 20 cm or more in diameter (figure 54), while multiple lesions tend to be smaller. PG ulcers can take years to heal and often require high-dose glucocorticoids and/or immuno-suppressant treatment, and leave behind atrophic, cribriform and often hyperpigmented scars.

Figure 54 *Pyoderma gangrenosum*.

5.3.2 Rheumatoid neutrophilic dermatitis

Rheumatoid neutrophilic dermatitis (RND) is a rare cutaneous finding in patients with severe RA. Clinically, the eruption is characterised by symmetric erythematous papules or plaques. Vesicles are sometimes seen on the extensor surfaces of the arms and hands.

Ulceration or progression to PG has not been described. On histological examination, a dense interstitial dermal neutrophilic infiltrate with leucocytoclasia without signs of leucocytoclastic vasculitis is seen. In most cases, topical treatment with potent glucocorticoids is sufficient.

Acute febrile neutrophilic dermatosis (Sweet's syndrome) may closely resemble RND on histology. Clinically, this neutrophilic dermatosis has a more acute onset with fever and develops with markedly inflamed and oedematous coin- or dome-shaped tender infiltrates and plaques, often on the shoulder and the face.

RA is one of the many known underlying disorders which also include upper respiratory tract infections, gastrointestinal disorders, drug reactions and leukaemia.

In contrast to PG, Sweet's syndrome can resolve spontaneously or with various treatments including colchicine, dapsone and steroids, without scarring. Despite the fever, antibiotics are ineffective in the cases not associated with infection; treatment of the underlying disorder is most important.

5.4 Cutaneous side effects of RA treatment

It is estimated that up to 40% of RA patients develop cutaneous drug adverse events in the course of their treatment. These reactions are mild in most cases, occur within the first few weeks of treatment, and manifest as vasculitis, urticaria or skin rash. The rash may be maculo-papular, vesiculous, bullous or pustular, often affecting the whole integument and the mucosal surfaces; the most severe of these allergic drug reactions to antirheumatic drugs are Stevens-Johnson syndrome (SJS) and TEN (Lyell syndrome), which have a high mortality rate, especially in older patients.

5.4.1 Non-steroidal anti-inflammatory drugs

Skin reactions to aspirin are rare (<1%) in the general population, but much more common among patients with asthma or chronic urticaria. These reactions are mostly of a non-immunological nature and are related to pharmacological intolerance and linked to arachidonic acid metabolism and leukotriene release. On the other hand, some non-steroidal anti-inflammatory drugs are credited with a high risk of allergic skin reactions ranging from transient rash resembling viral exanthema to TEN (such as the many pyrazol and pyrazolon derivatives, including oxicam). However, the absolute risks of SJS and TEN associated with NSAID treatment are low; oxicams have a higher risk of SJS and TEN than the other NSAIDs and patients who have recently begun treatment should be carefully monitored. Selective cyclo-oxygenase-2 inhibitors have been less frequently

reported to be associated with serious drug reactions and in fact seem to be well tolerated by most NSAID-sensitive and aspirin-intolerant patients.

5.4.2 Disease-modifying antirheumatic drugs

Sulfasalazine or its major metabolites 5-aminosalicylic acid and sulfapyridine can cause an itchy rash that usually resolves once the drugs are stopped. Sulfasalazine causes a peculiar orange-tinged discoloration of sweat. Rare adverse muco-cutaneous side effects include oral ulcers, hypersensitivity syndrome (lichenoid skin eruption, leucocytopenia, thrombocytopenia, fever) and SJS or TEN.

Chloroquine and hydroxychloroquine are known to induce a characteristic greyish-blue hyperpigmentation of glabrous skin and mucosal surfaces.

Muco-cutaneous side effects following the administration of gold compounds (oral or intramuscular) are estimated to occur in 10–20% of treated patients. Within weeks or months, a generalised rash, closely resembling lichen planus, pityriasis rosea or eczema may be seen; urticarial, hyperpigmented (Chrysiasis) or vasculitic lesions are less frequent, while SJS and TEN are extremely rare. Gold dermatitis often responds to topical treatment with mid-potent glucocorticoids, and continuation of treatment at a lower dosage may be tried.

Cutaneous toxicity from D-penicillamine can be a major problem requiring definite discontinuation of the drug; in addition to eczematous or lichenoid rashes, as seen with other antirheumatic medications, D-penicillamine can uniquely induce or exacerbate autoimmune diseases such as SLE, DM, myasthenia gravis and, most notably, pemphigus vulgaris or foliaceus. D-penicillamine contains sulfhydryl groups which are believed to have a key role in inducing direct lysis of the epidermis, through alteration of the intercellular bonds through the formation of thiol group–cysteine bonds, instead of cysteine–cysteine bonds.

5.4.3 Biologics

The introduction of biological therapies that target specific proinflammatory cytokines have had a great impact as new treatment options for patients with RA.

Adverse reactions to the IL-1 blocker anakinra and to the TNF- α inhibitors infliximab, etanercept and adalimumab have been estimated to occur in about 25% of RA patients treated with biologics (Scheinfeld, 2004*).

These cutaneous reactions are of special interest to dermatologists, since most biologics are also used for inflammatory skin disorders such as psoriasis.

5.4.3.1 Local reactions

Inflammatory reactions at injection sites are common in RA patients undergoing treatment with anakinra; treatment can be maintained in the great majority of cases. Similar erythematous or oedematous lesions occur mostly within 12–24 h following subcutaneous injection of etanercept and usually disappear within 3–5 days without topical treatment.

Matters of concern are generalised cutaneous reactions seen either immediately or after several days in 10–20% of RA patients following intravenous administration of infliximab; these reactions present with a disseminated erythematous flush or with acute urticaria and pruritus (figure 55). When these skin reactions recur with subsequent injections or are accompanied by systemic symptoms such as fever, dizziness or hypotension, termination of infliximab treatment may become necessary. However, an anaphylactic reaction to infliximab requiring intensive care is very rare.

Figure 55 *Acute urticarial rash induced by infliximab.*

5.4.3.2 Skin infections

About one third of skin changes related to treatment with biologics are infections. The most frequent are pityriasis versicolor caused by excessive proliferation of the saprophyte yeast *Malassezia spp.* and tinea corporis caused by several dermatophytes; less frequent are herpes simplex, zoster or bacterial infections.

5.4.3.3 Inflammatory skin eruptions

Generalised or localised inflammatory skin reactions resembling atopic dermatitis, eczema, psoriasis or lichen planus are the most frequent cutaneous adverse effects related to treatment with biologics. Psoriasiform eruptions seem to be a class effect common to infliximab, etanercept and adalimumab; the eruption may appear immediately after the first injection or several months later, and tends to become pustular, often resembling palmoplantar pustular psoriasis, especially in RA patients treated with infliximab; however, psoriasis vulgaris may also occur. The mechanisms involved remain elusive. In some patients, switching to another TNF- α blocker results in clearing of the skin, although in others discontinuation of biologics altogether and initiation of an antipsoriatic treatment is necessary.

5.4.3.4 Drug-induced lupus erythematosus

Antinuclear antibodies (ANA) are a frequent serological finding in RA patients treated with TNF- α inhibitors (table 4). Lupus erythematosus-like skin manifestations resembling SCLE, DLE or SLE are, however, very rare and are estimated to occur in less than 0.5% of RA patients treated with TNF- α inhibitors. About two-thirds of these patients have systemic manifestations typical of SLE and characterised by arthritis, polyserositis, myositis, vasculitis and other complications including renal disease; serologically, antibodies to double-stranded DNA and hypocomplementaemia are often present. TNF- α -induced SLE differs markedly from drug-induced SLE due to other medications. Other patients develop DLE with erythemato-squamous lesions in UV-exposed skin, alopecia, chilblain-like lesions, and vasculitis or overlap syndromes such as mixed connective tissue disease. In many patients, the lupus reaction resolves with cessation of TNF- α blocker treatment.

Table 4 Frequency of antinuclear antibodies during treatment with biologics

	ANA (%)	Anti-DNA IgM/IgA (%)	Anti- DNA IgG (%)
Infliximab	28–82	49–70	>5
Adalimumab	13–28	>10	–
Etanercept	5–10	>10	–

ANA, antinuclear antibodies.

Besides LE or lupus-like syndromes, other autoimmune diseases may develop during therapy with biologics; these include hypocomplementaemic systemic vasculitis and IgA-nephritis.

5.5 Cutaneous manifestations in subsets of RA

Cutaneous signs of Felty syndrome (a combination of RA, splenomegaly and neutropenia) consist of rheumatoid nodules, hyperpigmentation and leg ulcers. The incidence of rheumatoid nodules in Felty syndrome is about 70% and thus much higher than in RA. The leg ulcers resemble that shown in figure 53; they may be secondary to PG or medium blood vessel vasculitis with ulcerations. They are extremely resistant to treatment and at risk of becoming septic due to the underlying immune defects present in some patients with Felty syndrome.

6 Skin manifestations in Still's disease

In up to 90% of patients, systemic-onset juvenile idiopathic arthritis (Still's disease) is characterised by a typical transient, pink macular rash over the trunk, axillae, face and extremities that is non-pruritic and coincides with acute febrile episodes of the disease, occurring usually in the late afternoon. The patient's skin is hypersensitive, often demonstrating urticarial dermographism. Other cutaneous features include persistent linear and peri-orbital oedema and erythema. Rheumatoid nodules are rare but may appear in the course of treatment with methotrexate.

The transient, rash of adult-onset Still's disease also accompanies fever spikes and shows a characteristic salmon-pink colour. The rash is most often macular or slightly urticarial and appears over pressure points. It usually corresponds to a neutrophilic urticarial dermatosis when biopsied (Kieffer et al, 2009). Persistent red pruritic papules and plaques, sometimes linear, may be also seen in adult patients with more severe forms of Still's disease. A distinctive histopathological aspect associating dyskeratotic/necrotic cells in the upper epidermis and perivascular (and sometimes also interstitial) inflammatory infiltrate of lymphocytes and neutrophils in the upper and mid-dermis is observed.

The differential diagnosis of the rash in Still's disease includes various viral exanthemas, drug eruptions, and erythema marginatum rheumaticum seen in acute rheumatic fever. This rapidly spreading annular erythema occurs mostly on the trunk and is—in contrast to Still's disease—not associated with fever spikes.

SUMMARY POINTS

- Skin signs are present in more than 80% of lupus erythematosus (LE) cases. They can be divided into four groups: specific lupus lesions, lesions reflecting thrombotic vasculopathy, neutrophilic lupus and miscellaneous lesions. Lupus lesions include acute, subacute and chronic LE. All lupus skin types can be associated to varying degrees with systemic LE.
- Patients with subacute cutaneous LE can develop Gougerot-Sjögren syndrome and reciprocally. This association increases the risk of cutaneous vasculitis, central nervous system involvement and interstitial pulmonary syndrome.
- Sun protection, antimalarials and topical anti-inflammatory creams are the first-line treatment in cutaneous LE, except for neutrophilic LE where anti-neutrophil drugs (colchicine, dapsone) are the treatment of choice.
- Vascular manifestations in LE are rarely related to vasculitis (eg, urticaria) and more frequently to thrombosis (eg, livedo reticularis), implying specific therapeutic interventions (including anti-platelets and/or anticoagulants).
- Heliotrope oedematous erythema of the face and Gottron papules on the finger joints are highly specific of dermatomyositis (DM). Skin calcinosis is a major problem, especially in childhood DM.
- Skin necrosis, skin vasculitis, pruritis and bullous lesions are suggestive of underlying malignancy in adult DM, generally in association with the presence of anti-TIF-1gamma or anti-NXP2 autoantibodies.
- Diagnostic criteria for systemic scleroderma (SS) are skin thickening of the fingers extending proximal to the metacarpophalangeal joints or if that sign is not present, seven additive items are considered, with varying weights for each: skin thickening of the fingers, fingertip lesions, telangiectasia, abnormal nailfold capillaries, interstitial lung disease or pulmonary arterial hypertension, Raynaud's phenomenon and SS-related autoantibodies.
- Skin involvement in SS can be limited to acral areas (hands, feet), the face and the neck or can be diffuse, ascending to the trunk and abdomen. Diffuse skin involvement is associated with multiple internal manifestations and a poorer outcome.
- Fingertip ulcers are a major clinical problem in diffuse cutaneous scleroderma and are frequently associated with Raynaud's syndrome, lung fibrosis and pulmonary arterial hypertension.
- Purpura is the most frequent skin lesion in systemic vasculitis. Cutaneous manifestations are important for confirming the vasculitis, but are rarely suggestive of the type of vasculitis.
- Painful, non-healing skin ulceration is often associated with organ involvement in systemic vasculitis.
- Rheumatoid nodules are the most frequent extra-articular manifestation of rheumatoid arthritis (RA).
- Rheumatoid vasculitis and pyoderma gangrenosum in RA is indicative of advanced disease and poor prognosis.
- Cutaneous side effects of antirheumatic drugs occur in up to 40% of RA patients and range from transient skin rashes to life-threatening toxic epidermal necrolysis.
- In RA patients treated with TNF- α blockers, antinuclear antibodies frequently develop but clinical manifestations of LE are very rare.

IN-DEPTH DISCUSSION I

Differential diagnosis of scleroderma

Scleroderma, meaning "hard skin" in Greek, designs a heterogeneous group of auto-immune fibrosing affections including systemic sclerosis (SSc) and localized scleroderma, which should be better named morphea in our opinion. They share cutaneous induration, consecutive to sclerosis, as a common feature. However, a number of other diseases can also manifest with skin induration and sometimes systemic signs, the distinction with SSc being then crucial to ensure an appropriate and prompt management. Keys to the proper recognition of these scleroderma-like disorders (or sclerodermiform syndromes) are presented in this in-depth discussion. The sclerotic variant of the Graft vs Host disease should be rather considered as an experimental form of morphea than a differential diagnosis, and will not be addressed here.

1. Systemic sclerosis

A detailed description of SSc is available in the main text of module 29a, thus all these features will not be extensively reviewed here. Briefly, the cardinal elements of early SS's diagnosis are:

- Raynaud's phenomenon (RP), which is present in almost all patients, most often as the first sign of disease.
- Symmetrical cutaneous involvement of extremities, typically beginning as finger and/or toe oedema with mild erythema and puffy appearance, slowly progressing to skin sclerosis (sclerodactyly). Of note, skin sclerosis may rarely be absent in some patients with organ involvement (SSc sine scleroderma).
- Anti-nuclear antibodies (ANA), mostly of the anti-centromere, anti-topoisomerase I (Scl-70) or anti-RNA polymerase III type, which collectively are present in up to 95% of patients.

Additional highly suggestive cutaneous features are the abnormal rounded-to-rectangular telangiectasia located on the palmar aspect of the hands and fingers and the face (including the lips and oral mucosa), megacapillaries of the nailfold and pitted scars of the fingertips, lateral aspect of digits and sometimes dorsum of interphalangeal and metacarpophalangeal joints.

In the absence of both RP and ANA in a patient with sclerotic skin changes, the diagnosis of SSc is highly unlikely, meaning that another SS-like disorder should definitely be considered (Cheeseburger et al, 2012).

2. Morphea (localized scleroderma, including eosinophilic fasciitis)

Morphea is a fibrosing disorder of unknown aetiology affecting less than 3 per 100,000 inhabitants per year, with similar prevalence in children and adults. Multiple environmental factors (infections, skin trauma, radiations...) have been proposed to contribute to disease development (Mertens et al, 2017).

Superficial plaque morphea typically starts as a round or oval lilac patch which progressively evolves to central sclerosis giving a shiny ivory aspect surrounded by a peripheral active lilac ring. In the late phase, sclerosis often regresses to leave atrophy and/or pigmentary changes (figure 1).

Figure 1 Late stage of superficial plaque morphea.

Rare variants are guttate morphea (small white patches < 2 cm), bullous morphea and choroidal morphea. Multiple plaques of morphea may coexist (disseminated plaque morphea). A highly prevalent association exists between plaque morphea and genital lichen sclerosis (figure 2), concerning up to 38% of adult patients (Lutz et al, 2012).

Figure 2 Genital lichen sclerosis associated with plaque morphea. Complete atrophy of minor labia and clitoris hood.

As genital lichen sclerosus bears a risk of evolution into squamous cell carcinoma, full-body examination of patients with morphea by an experienced dermatologist is mandatory. This significant association has not been observed in patients with SSc yet, but such an association might exist, to a lesser degree, in patients with localized systemic sclerosis (D. Lipsker, manuscript in preparation). *Linear morphea* (including the “coup de sabre” variant and Parry-Romberg hemifacial atrophy) predominantly affects young individuals; deep involvement with bone defects may be present.

Deep morphea (or morphea profunda) predominantly involves hypodermis and/or fascia and manifests as poorly defined deep induration with sometimes cobblestone or “peau d’orange” appearance of the overlying skin.

Eosinophilic (Schulman’s) fasciitis (EF) is considered as a variant of deep morphea. Classically, it follows intense and unusual physical activity. Other triggering factors such as infection with *Borrelia burgdorferi*, auto-immune diseases or exposure to certain medications have been described. EF begins as symmetrical burning erythema and pitting oedema evolving to severe induration, affecting the limbs and sometimes the trunk. The skin appears bounded down to the underlying structures, with typical peau d’orange aspect (figure 3) and guttering around the superficial vessel (groove sign).

Figure 3 Eosinophilis fasciitis. Deep induration and peau d’orange appearance.

The fingers / toes and the face are always spared and RP is absent, ruling out SSc. Typical superficial plaque morphea is associated in 20-40% of cases. Hypereosinophilia is a variable transient feature. Considerable

functional impairment may result from joint contracture, thus early diagnosis and treatment are mandatory. MRI is helpful to document deep fascial involvement, guiding the deep surgical biopsy which should sample not only hypodermis but also fascia and superficial muscle to confirm the diagnosis. Sclerosis and tissue eosinophilia are characteristic histological findings. Underlying hematologic disorder of both lymphoid and myeloid type may be present in up to 10% of patients and should thus always be ruled out. Exposure to dietary supplements containing L-tryptophan or 5-hydroxytryptophan should be searched, as it can induce a highly similar picture with prominent myalgia (*eosinophilia myalgia syndrome*).

Generalized morphea is used to designate two distinct entities: *disseminated plaque morphea* (i.e. multiple plaque morphea), and *pansclerotic morphea*. The latter is a debilitating disease consisting in extensive, circumferential morphea starting on the trunk, which progresses to involve the majority of skin surface, but typically spares the fingers, toes and areolae. RP and nail fold capillary changes are absent, but ANA may be present, of the anti-single strand DNA and/or anti-histone type. Major functional disablement due to joint contractures and restrictive respiratory insufficiency is frequent, sometimes leading to death (Kim et al, 2014).

3. Differential diagnosis of acrosclerosis / sclerodactyly

SSc is not the only cause of sclerodactyly, and other conditions may present with sclerotic changes involving the skin of fingers (Ferrelli et al, 2017).

Among them, *mixed connective tissue disease* (Sharp's syndrome, MCTD) and *POEMS* (Polyneuropathy, Organomegaly, Endocrinopathy, Monoclonal protein, Skin changes) *syndrome* are the only two where RP may also be present. Typical cutaneous presentation of MCTD is erythematous puffy fingers with RP, but evolution to genuine sclerodactyly with nail fold capillary changes has been observed in a few cases, attesting a common spectrum from MCTD to SSc. Skin sclerosis has been reported in acral regions in 10% of POEMS patients, more rarely on the trunk or in a diffuse manner, while RP is present in 20% (Miest et al, 2013). Other skin changes suggestive of this monoclonal plasma cell proliferative disorder-associated syndrome are hyperpigmentation and hypertrichosis (often prominent on the extremities) and angiomatous papules corresponding to glomeruloid haemangiomas histologically.

Genuine sclerodactyly may also be encountered in various conditions such as:

- *porphyria cutanea tarda*, a metabolic disorder caused by dysfunction of hepatic uroporphyrinogen decarboxylase, either in a hereditary context or acquired in association with hemochromatosis, HIV or hepatitis C infection; prominent features of this condition are recurrent blisters on light-exposed areas leaving atrophic scars and milia, pigmentary changes and malar hypertrichosis (figure 4),

Figure 4 *Porphyria cutanea tarda. Sclerodactyly, dried blisters and atrophic scars*

- *carcinoid syndrome*, generally in the context of a digestive or pulmonary neuroendocrine tumours with hepatic metastases, in association with prominent flushing, diarrhoeas and bronchospasm,
- rare genetic diseases, generally obvious because of other suggestive features such as progeroid changes in *Werner's syndrome*, OMIM#277700; or keratoderma of the palm and soles in *sclerotoses* or Huriez syndrome, OMIM#181600).

Other conditions may resemble sclerodactyly but differ according to precise clinical analysis. In *fibroblastic rheumatism*, only palmar aspect of the hands is concerned by sclerosis, and para-articular flesh-coloured nodules are present. In *diabetic cheiroarthropathy*, confluent tiny waxy papules on the dorsum of fingers are responsible for skin induration, leading to flexural joint contractures, generally in the context of patients with long-standing juvenile-onset diabetes mellitus. In *palmar fasciitis and polyarthritits*, a paraneoplastic syndrome associated with ovarian and other cancers, diffuse inflammation of the palmar fascia and tendon sheaths is leading to flexion contracture of the hands without skin sclerosis. In *scleroderma-like amyloidosis* (see below), extremities can be involved, but induration and limitation of movements are not related to sclerosis, but to deposition of amyloid.

4. Differential diagnosis of non-acral skin sclerosis

Beyond diffuse morphea (either EF or pansclerotic morphea), other conditions are classically cited as differential diagnoses of diffuse SSc (Ferrell C et al, 2017; Tyndall et al, 2013). A distinction can generally be easily made on the basis of a careful skin examination, good anamnesis and serum protein electrophoresis plus immunofixation.

Scleromyxedema (or papular mucinosis) presents with an eruption of small waxy dome-shaped or flat-topped papules, often arranged in a linear pattern, with variable erythema and pruritus. Extensor surfaces of limbs, head, neck and trunk are progressively involved in a diffuse manner, with subsequent induration and movement

restriction. A monoclonal gammopathy, usually of the IgG lambda type, is often present (> 80% of cases). Central and peripheral nervous system involvement is frequent, sometimes leading to coma (dermato-neuro syndrome); polyarthralgia or even arthritis may also be present. Thyroid disease should be ruled out. Skin histology demonstrates a triad of dermal mucin deposits, fibrosis and fibroblast proliferation. Scleromyxedema typically exemplifies the concept of monoclonal gammopathy of cutaneous significance (Lipsker, 2017).

Scleredema (Buschke's) predominantly affects men with diabetes mellitus, but forms associated with upper respiratory tract infections or monoclonal gammopathy in the absence of diabetes have been described. It presents with progressive indurated non-pitting oedema of posterior neck and shoulders, with faint erythema and peau d'orange aspect. Extension to the face impairing facial expression is possible, while systemic involvement is rather infrequent. Abundant dermal mucin deposits and septal fibrosis are the main histological anomalies.

Nephrogenic systemic fibrosis is a disease linked to organ deposition of gadolinium-based contrast agents, mainly gadodiamide, subsequent to MRI performed in patients with advanced renal failure (i.e. eGFR <30 mL/min/1.73 m²) and first reported in 2000. The number of new cases has declined dramatically since the cause was identified in 2006. However, the disease can reveal itself years after exposure. It presents with firm and sometimes erythematous and itchy papules coalescing in plaques and / or deep nodules symmetrically distributed on the limbs and the trunk, the face and the fingers / toes being usually spared (figure 5). A suggestive cobblestone or peau d'orange aspect of the skin is often present. Impairment of joint flexibility subsequent to fibrosis and systemic involvement affecting heart and lungs may occur. Histological analysis shows a proliferation of fibroblasts with thickening of collagen bundles that extends into the hypodermis.

Figure 5 Nephrogenic systemic fibrosis. Waxy coalescent papules on a limb.

Scleroderma-like amyloidosis is an extremely rare variant of light chain amyloidosis. Induration of skin can be widespread and can also involve extremities. Skin biopsy will show deposition of amyloid material in the dermis and sometimes hypodermis by Congo-red stain.

IN-DEPTH DISCUSSION II

**Cutaneous manifestations of antiphospholipid syndrome
(APS)**

Antiphospholipid Syndrome (APS) is the association of antiphospholipid antibodies (aPL) with hypercoagulability resulting in arterial and/or venous thrombosis, and pregnancy morbidity/obstetric complications (1). Since the first description of antiphospholipid syndrome in 1983 (2), a wide variety of dermatologic manifestations (table I) have been reported (1). Their clinical significance is highly variable. Their management depends on clinical aggressiveness and the presence of other manifestations of APS.

Skin manifestations of APS

A convenient way to classify skin manifestations of APS is to distinguish between lesions reflecting microangiopathy and lesions reflecting large vessels thromboembolic disease. This distinction makes sense as pathophysiology likely differs in some way, which may result in different management strategies (as vascular and heart imaging in the case of large vessel thromboembolism for example).

1. Lesions reflecting microangiopathy

Livedo of the racemose type (LR) is the most frequent dermatologic manifestation. It has been described in sixteen to twenty five percent of two large series of cases (3, 4) and was the inaugural feature of APS in seventeen percent of cases. It is usually extensive or may be localized on the limbs, the trunk and the buttocks. The fishnet reticular pattern is fine and irregular realizing incomplete broken circles (fig. 1). Unlike vasculitic LR, APL livedo is not infiltrated and non-tender. The mechanism of LR in APS remains unclear. Histopathology of skin biopsies (whatever the site sample is) does not show thrombosis except in the catastrophic APS subtype. Vascular proliferation and endarteritis obliterans of arterioles (5) have been reported in some cases. These features do not exclude previous patchy thrombosis. Interaction of antiphospholipid antibodies with the endothelium or other cellular elements of the vessels, in a way that alters their function and induces vasoconstriction, is another possible mechanism (6). In our opinion, LR has to be considered as sequelae and not as an active lesion, in the sense that it won't further evolve to skin necrosis. This doesn't hamper its pathologic significance however, as the underlying thrombotic process may be active in other organs at the same time.

Figure 1: Livedo racemosa in SLE-related APS

Livedoid vasculopathy-like lesions are painful necrotic ulcers located on the legs, ankles and dorsum of feet. It presents as a small painful purpuric macule evolving to a larger geographic-shaped ulceration with purple non- or slightly elevated borders. Healing time is slow, leaving atrophie blanche when achieved. It may be the sole clinical manifestation of APS (fig.2). When a biopsy is performed, small vessel thrombosis may be hard to demonstrate.

Figure 2: Typical atrophic scars of livedoid vasculitis-like ulcers with purpuric necrotic lesions in primary APS

Retiform purpura is likely the most alarming manifestation of APS, as it reflects complete vascular occlusion with vascular damage leading to red blood cells extravasation. It manifests as well-defined angular or branched red to purple macules that fail to blanch under pressure, generally evolving to **superficial gangrene**. It is important to note that small distal lesions of retiform purpura may also be observed in the context of large vessels thromboembolism.

Rapidly extensive retiform purpura (mimicking infectious purpura fulminans) leading to **widespread superficial cutaneous necrosis** may be observed in catastrophic APS, the most severe and fortunately infrequent form of APS, characterised by widespread small-vessel thrombosis with multiorgan failure and high mortality (7). Cutaneous lesions are similar to those observed in other thrombophilic states such as protein C or protein S deficiencies, monoclonal cryoglobulinaemia or cryofibrinogenaemia (fig. 3). Histopathology of early purpuric lesions shows diffuse skin vessels thrombosis, without associated inflammation.

Figure 3: Widespread superficial skin necrosis in SLE-related APS

Other lesions reflecting thrombotic microangiopathy in APS are **pseudovasculitis lesions** mimicking cutaneous vasculitis that may be misdiagnosed if skin biopsies are not performed, especially in case of SLE; ill-defined **purpura** (fig. 4); papules or nodules of the limbs, ears, neck or thighs, and **malignant atrophic papulosis-like lesions** (fig. 5). Thrombosis of skin vessels and acellular mucin-rich dermis is usually obvious on biopsies in the latter. The term “vasculitis” is misleading in those cases, which reflect a primary thrombotic vasculopathy and not an inflammatory process affecting the vessel wall.

Pyoderma gangrenosum-like large ulcers have rarely been described on the legs of patients with APS, differing from genuine pyoderma gangrenosum as they lacked undermined elevated borders and demonstrated prominent small vessels thrombosis instead of neutrophilic infiltrate on histology.

Figure 4: Purpuric lesions related to thrombosis can be extremely difficult to distinguish from purpuric lesions related to vasculitis

Figure 5: Malignant atrophic papulosis-like lesions of the digit

2. Lesions reflecting large-vessels thromboembolism

Superficial and deep venous thromboses are common manifestations of APS which may result in common secondary skin changes such as **lipodermatosclerosis** or **venous ulcers**.

Distal gangrene (often preceded by **acrocyanosis** and/or **purple toe or digit**) may reflect distinct pathomechanisms involving large vessels, ranging from acute to slowly evolving processes:

- stenosis or occlusion of medium to large arteries,
- atheroembolism from a ruptured atherosclerotic plaque, heart valve vegetation or intracardiac thrombus,
- venous limb gangrene resulting from phlegmasia cerulea dolens, usually in the setting of catastrophic APS (8).

Multiple splinter haemorrhages under the nails appear as tiny linear longitudinally oriented, reddish-brown to black, distal lesions that fail to blanch under pressure (fig. 6). They may be also observed in various conditions implying or not distal embolism, e.g. subacute bacterial endocarditis, and even in healthy people (9).

Figure 6: Multiple splinter haemorrhages of the nails concomitant to pulmonary embolism in APS

3. Other skin manifestations associated with APS

Primary anetoderma (fig. 7) is a rare elastolytic disorder, characterized clinically by a circumscribed area of slack skin with macular depressions or out-pouchings of skin. Skin lesions are numerous (>10), located on the upper part of chest and arms. Histologically there is a loss of dermal elastic tissue. Anetoderma may be primary or secondary to various dermatoses. When primary, it is frequently observed in patients with autoimmune diseases and especially related to antiphospholipid antibodies (10).

Figure 7: Diffuse anetoderma in SLE-related APS

Relevance of dermatologic manifestations in the diagnosis of APS

In the latest international consensus statement to define APS (table II), clinical criteria include skin vessels thrombosis on strict condition that thrombosis is confirmed by histopathology, with the exception of superficial venous thrombosis (11). As previously stated, thrombosis is rarely detected on skin biopsies of patients with livedo only. Biopsy of splinter haemorrhages of the nails is exceptionally done. On the contrary, thrombosis may be detected in biopsies of all other skin lesions.

Association of skin lesions to other manifestations of APS

LR is significantly correlated with cerebral and ocular ischemic arterial events, seizures, heart valve thickening on ultrasound, and arterial systemic hypertension. Conversely, LR is less frequent in patients with only venous thrombosis (3, 4). Post phlebitic ulcers are correlated with recurrent venous thrombosis,

The onset of multiple splinter haemorrhages of the nails is frequently concomitant to worrying thrombotic events of various sites (brain, digits, skin, adrenal glands...) (9).

The “catastrophic” APS is characterized by widespread vascular occlusions involving multiple organs simultaneously. It is frequently associated with skin lesions (70%). LR, acrocyanosis, extensive cutaneous necrosis, palmar erythema, digital gangrene and ischemic ulcers have been reported in this condition (7).

Treatment

Treatment of patients with skin lesions must be considered according to the different dermatologic manifestations and the clinical situation. Two questions should be answered: (a) how to treat dermatologic manifestations? And, (b) is any prophylactic long term-treatment required in such patients? In the absence of randomized controlled trials, therapy of skin lesions remains empirical.

Widespread cutaneous necrosis and/or digital gangrene are the major thrombotic events that require full anticoagulation with heparin. If extension of these skin lesions persists despite anticoagulation, prostacyclin derivatives and/or plasmapheresis may be prescribed as they have been reported to be successful in isolated cases.

No treatment has been proven to be effective in LR. In our experience, LR may extend or appear despite anticoagulant or anti-platelet therapy. LR is less visible on sun-tanned skin; but sun exposure is not recommended in SLE-related APS.

In isolated other skin lesions such as livedoid vasculitis-like ulcers or pseudo-vasculitis lesions, low dose-aspirin and dipyridamole has been reported to be effective in some patients. If such lesions recur or extend despite anti-platelet agents, anticoagulation with low molecular weight heparin is usually prescribed.

Prevention of recurrence of skin lesions depends not only on the severity of these skin lesions, but also on the other features of the disease. As widespread cutaneous necrosis and/or digital gangrene are considered to be major thrombotic events, the current recommendations for such cases are long term high-intensity warfarin (INR 2.5-3.5).

In the absence of large vessel occlusion, prevention of recurrence of the “minor dermatological manifestations” (i.e. livedoid vasculitis-like ulcers, pseudo-vasculitis skin lesions) is unclear. Antiplatelet therapy such as low-

dose aspirin (75 mg/day) is frequently a logical first choice treatment. Hydroxychloroquine has also well-documented anti-platelet effect and has been shown to reduce the risk of thrombosis in both SLE patients and animal models of APS. However, in our experience, these treatments are frequently insufficient and long term anticoagulation is often required.

The place of other therapeutic options such as rituximab or inhibitors of the mammalian target of rapamycin (mTor) remains to be determined (12).

Whatever the type of skin lesions is, it is important to eradicate or reduce other risk factors of thrombosis. Among others, patients are advised to stop smoking and using oestrogen-containing pills, obtain a perfect control of cardiovascular risk factors (tension, cholesterol) and a regular physical activity is recommended.

Table 1: Dermatologic manifestations of the antiphospholipid syndrome with supposed pathomechanisms

Thrombotic microangiopathy	Livedo racemosa Livedoid vasculopathy-like ulcers Large ulceration resembling pyoderma gangrenosum - Pseudo-vasculitis lesions - purpura - palmar or plantar erythema - nodules - pustules - malignant atrophic papulosis-like lesions Retiform purpura and superficial skin necrosis
Large-vessel thromboembolism	Superficial phlebitis Post phlebitic skin ulcers Acrocyanosis, purple toe / digit Multiple splinter haemorrhages under the nails Digital gangrenes
Other	Anetoderma

Table II: International consensus statement: Classification criteria for definite APS**Clinical criteria****- Vascular thrombosis**

One or more clinical episodes of arterial, venous, or small vessel thrombosis, in any tissue or organ. Thrombosis must be confirmed by imaging or Doppler studies or histopathology, with the exception of superficial venous thrombosis. For histopathological confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.

- Pregnancy morbidity

- a) One or more unexplained deaths of a morphologically normal foetus at or beyond the 10th weeks of gestation, with normal foetal morphology documented by ultrasound or by direct examination of the foetus, or
- b) One or more premature births of a morphologically normal neonate at or before the 34th week of gestation because of severe pre-eclampsia or eclampsia, or severe placental insufficiency or
- c) Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded.

Laboratory criteria

- 1) **Lupus anticoagulant** present in plasma, detected according to the guide-lines of the International Society on Thrombosis and Haemostasis
- 2) **Anticardiolipin antibody** of IgG and/or IgM isotype in blood, present in medium or high titer (> 40 GPL or MPL or > the 99th percentile; detection by a standardized ELISA method)
- 3) **Anti-b2 glycoprotein 1 antibody of IgG and/or IgM isotype** (titer > the 99th percentile, detection by a standardized ELISA method according to the recommended procedure)

Classification of APS should be avoided if less than 12 weeks or more than

5 years separate the + aPL tests and the clinical manifestations. aPL tests have to be positive on two or more occasions, at least 12 weeks apart

Definite APS is considered to be present if at least one of the clinical and one of the laboratory criteria are met.

Osteoarthritis: pathogenesis, clinical aspects and diagnosis

Augustin Latourte, Pascal Richette, Rik Lories

A previous version was coauthored by Rik Lories, Barbara Neerinckx, Francis Berenbaum, Rani Liu, Margreet Kloppenburg, Jérémie Sellam, Gabriel Herrero-Beaumont

LEARNING OBJECTIVES

- Describe the key processes, cell types and the main soluble mediators involved in the pathogenesis of osteoarthritis.
- Outline the main clinical features of osteoarthritis and the specific signs according to the localization.
- Understand risk factors for initiation and for progression of osteoarthritis.
- Explain advantages and limitations of different imaging methods for the diagnosis and assessment of osteoarthritis and their respective utility in daily practice.
- Understand and use standardized tools used to assess pain, function and structural damage in the field of osteoarthritis.
- Get insights into the use of diagnostic recommendations and the value and limitations of classification criteria in the field of osteoarthritis.

1 Summary

Osteoarthritis (OA) is the most common chronic joint disorder. It usually results in joint pain, stiffness, deformity and loss of function, ultimately leading to chronic disability. OA mainly affects the elderly but should not be considered a simple consequence of aging. The American College of Rheumatology defined OA as ‘a heterogeneous group of conditions that lead to joint symptoms and signs which are associated with defective integrity of articular cartilage, in addition to related changes in the underlying bone and at the joint margins’ (Altman et al, 1986). The American Academy of Orthopaedic Surgeons has provided a more extensive definition: ‘OA is the result of both mechanical and biological events that destabilize the normal coupling of degradation and synthesis of articular cartilage and subchondral bone. Although it may be initiated by multiple factors including genetic, developmental, metabolic and traumatic, OA involves all of the tissues of the diarthrodial joint. Ultimately, OA is manifested by morphologic, biochemical, molecular and biomechanical changes of both cells and matrix which lead to softening, fibrillation, ulceration and loss of articular cartilage, sclerosis and eburnation of subchondral bone, osteophytes and subchondral cysts. When clinically evident, OA is characterised by joint pain, tenderness, limitation of movement, crepitus, occasional effusion, and variable degrees of local inflammation’ (Kuettner and Goldberg, 1995).

The burden of OA and associated healthcare expenditures are enormous. In 2002, the World Health Organisation identified OA as the fourth leading global cause of years lived with disability (YLD) (WHO, 2002). An update in 2015 shows that OA is still in the top 30 YLD causes, and that its burden is steadily increasing (GBD 2015, 2016). OA affects an increasing proportion of people, due to the obesity pandemic and overall aging of the population. Therefore, there are serious individual and societal challenges (Hunter et al, 2014).

The above definitions highlight the fact that OA is no longer considered a ‘degenerative’ or ‘tear and wear’ disease but the result of active biochemical, biomechanical and cellular processes. In addition, OA pathophysiology is now viewed not from a chondrocentric position but rather as a disease of the whole joint organ, involving the different structures and influencing their functional interaction. In addition to the focal lesions of the articular cartilage, combined with a hypertrophic reaction (sclerosis) in the subchondral bone and new bone formation (osteophytes) at the joint margin, peri-articular muscle weakness, lax ligaments, low-grade synovitis, meniscal degeneration and neurosensory system alterations all actively contribute to the onset and progression of disease.

Optimal management requires early diagnosis and awareness of the risk factors that can affect prognosis. Diagnosis should be made on clinical grounds with imaging as an additional tool. Different tools and imaging options are available for assessing the severity, impact and progression of disease.

2 Pathology of OA

2.1 A disease of the whole joint

OA is characterised by damage to the articular cartilage, osteophyte formation at the joint margins, subchondral bone sclerosis, and synovial and joint capsule thickening. These changes lead to joint degeneration and associated symptoms: pain, tenderness, stiffness, loss of function and disability. Changes in the individual tissues of the joint affect both tissue homeostasis and the functional cooperation between the joint tissues necessary for maintaining the function of the joint as an organ. Understanding the cellular and molecular processes and mediators involved as well as the communication between cells and tissues should lead to the identification of therapeutic targets and the development of specific strategies to prevent, treat and cure OA.

The main macroscopic changes in an osteoarthritic joint are highlighted in figure 1:

Figure 1 Anatomy of the joint and typical changes associated with osteoarthritis. Typical X-ray changes are highlighted next to the schematic presentation. Osteoarthritis is characterised by loss of cartilage, joint space narrowing, synovial hyperplasia, subchondral bone sclerosis and osteophyte formation. (Reproduced with permission from Luyten et al, Bone 2009;44:522–7.)

- Reduced joint space related to loss of articular cartilage
- Subchondral bone with hypertrophic reaction (sclerosis) and new bone formation (osteophytes) at the joint margins
- Inflammation and hyperplasia of the synovial membrane and joint capsule.

2.2 Breakdown of articular cartilage

Articular cartilage is a connective tissue composed of the articular chondrocytes as the unique cell type and of extracellular matrix (ECM) or ground substance which contains collagen (mainly type II fibrils associated with

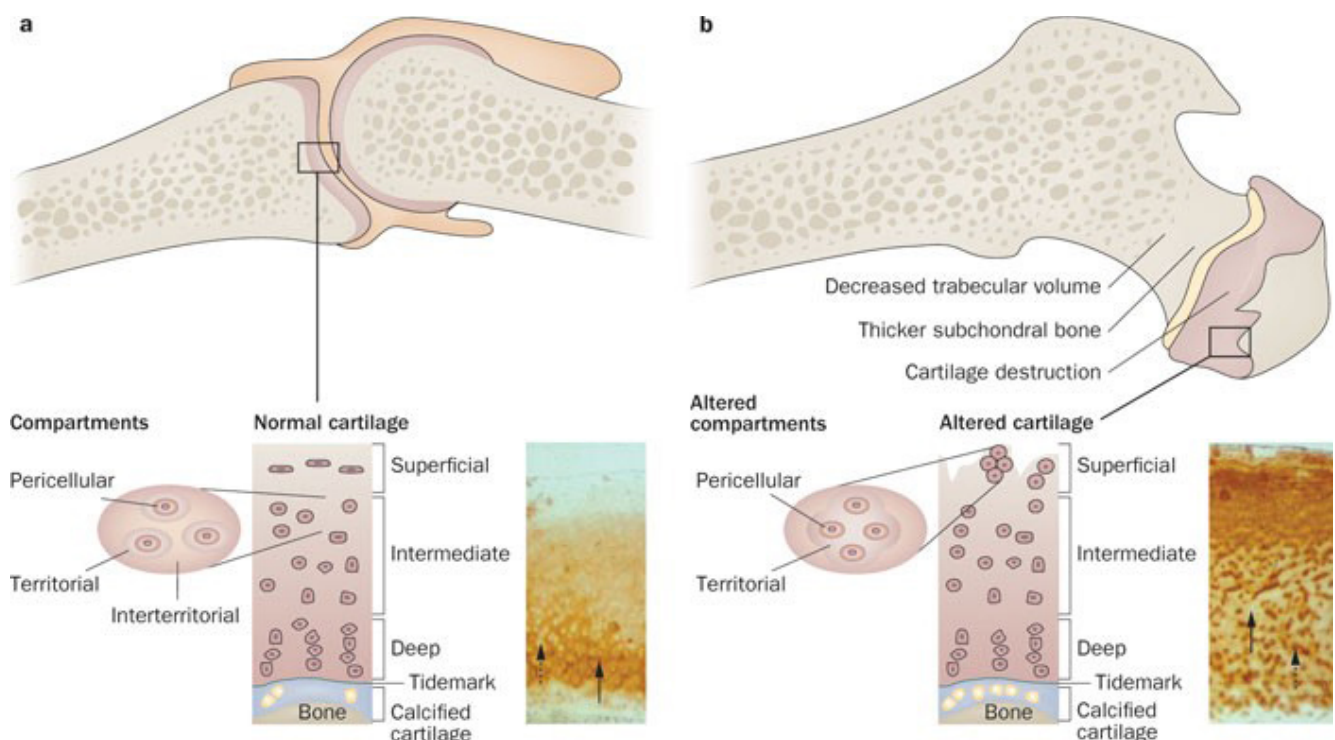

both collagen IX and XI) and proteoglycans. ECM composition defines the biomechanical properties of the articular cartilage. Type II collagen forms highly cross-linked fibrils of triple helix molecules that interact with other collagens and the proteoglycans (figure 2). The collagen fibrils form an organised network that entraps the proteoglycans. Aggrecan is the main proteoglycan in cartilage (figure 2). It consists of a central core protein bearing numerous glycosaminoglycan chains of chondroitin sulfate and keratan sulfate. The side chains are strongly negatively charged and attract polar H₂O molecules. Aggrecan non-covalently associates with hyaluronic acid (HA), a linkage stabilised by link protein. HA binds up to 100 aggrecans and the resulting molecular complexes form the major structural component of articular cartilage giving the cartilage its functional properties such as compressibility and elasticity due to the shift of H₂O molecules (Heinegård and Saxne, 2011). The collagen network provides stability and resistance against shear forces.

Figure 2 The molecular organisation of normal articular cartilage. The cartilage matrix surrounding chondrocytes in healthy articular cartilage is arranged into zones defined by their distance from the cell. The pericellular matrix lies immediately around the cell and it is the zone where molecules that interact with cell surface receptors are located; for example, hyaluronan binds the receptor CD44. The territorial matrix is next to the pericellular matrix, slightly further from the cell. The interterritorial matrix is furthest from the cell. The types of collagens and the collagen-binding proteins that constitute the matrices are different in each zone. CILP-1, cartilage intermediate layer protein 1; COMP, cartilage oligomeric matrix protein; CS, chondroitin sulfate; KS, keratan sulfate; PRELP, proline-arginine-rich end leucine-rich repeat protein. (Reproduced with permission from Heinegård and Saxne, Nat Rev Rheumatol 2011;7:50–6.)

Under ideal physiological circumstances, the water-rich articular cartilage forms a soft cap on top of the bones, allowing smooth movement and transition between the bony bearings of the skeleton. In the first stages of disease, before clinical signs and symptoms start to develop, the smooth surface of the articular cartilage becomes roughened with small irregularities and superficial clefts. As the disease progresses, the cracks become deeper, extending into the middle zone of the cartilage. Lesions may grow and connect, thereby increasing the damaged surface. Clefts become focal erosions and ulcerations, ultimately exposing parts of the underlying bone (figure 3).

Figure 3 Properties of normal and osteoarthritic joints. (A) A healthy joint with normal articular cartilage. The articular cartilage is organised into pericellular, territorial and interterritorial matrices, each of which is present at a specific distance from the chondrocytes. On immunohistochemistry (see inset images), the territorial and pericellular matrices (dashed arrow) show essentially no staining for cartilage oligomeric matrix protein (COMP), whereas the interterritorial matrix stains positive for this cartilage extracellular matrix molecule (solid arrow). **(B) An osteoarthritic joint, which shows partial loss of cartilage and alterations in the underlying bone.** The cartilage compartments are altered even at early stages of disease, and demonstrate cloning and multiplication of cells. However, the immunohistochemistry findings show that cloning is not yet prominent. Loss of COMP staining is evident in the interterritorial matrix (solid arrow) at the same time as the new synthesis of the molecule results in deposition primarily in the pericellular matrix of the cartilage (dashed arrow). (Reproduced with permission from Heinegård and Saxne, *Nat Rev Rheumatol* 2011;7:50–6.)

Chondrocytes are the only cells found in the ECM and are responsible for the production, maintenance, remodelling and eventually destruction of the cartilaginous matrix. Chondrocytes have low metabolic activity and survive under relatively hypoxic conditions. The synovial fluid and subchondral bone provide nutriment,

maintaining chondrocyte cellular activities. Hypoxia modulates the intracellular expression of survival factors, such as hypoxia-inducible factor-1 α (HIF-1 α), which support the survival of chondrocytes and respond to environmental changes (Goldring and Goldring, 2010). The chondrocyte itself possesses limited regenerative capacity, and so significant traumatic cartilage injuries often predispose to OA (Dell'Accio and Vincent, 2010).

In the early stages of OA, the quiescence of the chondrocytes is disrupted and cells appear to adapt to local stresses such as direct damage or biomechanical strain (figure 4). Proliferating cells can be found, often in clusters. In addition to increased matrix synthesis (type II collagen and aggrecan), some of the chondrocytes also lose their stable molecular characteristics and start expressing markers and molecules associated with hypertrophic chondrocytes. Except for the transition zone of calcified cartilage between the deeper layers of the articular cartilage and the subchondral bone, such cells are not present in the adult joint (see also figure 3 – the tidemark is a histological feature that separates calcified and non-calcified matrix). The hypertrophic chondrocytes represent a terminal differentiation state during development and growth (growth plate) and typically produce collagen type X molecules, vascular endothelial growth factor (VEGF) and matrix metalloproteinase 13. This process affects the properties of the ECM. As outlined in more detail below, the initial response of the chondrocytes also has other negative effects as the cells also release matrix-degrading enzymes and inflammatory cytokines that contribute to progressive destruction. Another important feature of OA is chondrocyte cell death, which apparently can occur through apoptosis and necrosis.

2.3 Subchondral bone remodelling

Parallel changes in the subchondral bone are being elucidated (Funck-Brentano and Cohen-Solal, 2015). When exposed by loss of cartilage, the subchondral bone acquires an ivory-like aspect, a dense substance with a smooth surface. This process is called eburnation. The relationship and primacy of changes in cartilage and bone have been extensively debated (Brandt et al, 2006; Lories and Luyten, 2011; Mahjoub et al, 2012). From a practical point of view, it seems that both processes mutually influence each other and co-contribute to progression of disease (Karsdal et al, 2014). In addition, osteophytes, which are bony outgrowths, are formed at the joint margins. Other features in the bone include the formation of subchondral cysts (secondary to influx of synovial fluid or local necrosis of bone) and areas of bone marrow oedema (which can be recognised on MRI imaging). Such bone marrow lesions are considered predictors of OA progression, with biomechanical factors such as limb alignment playing a likely role (Felson et al, 2003). Subchondral bone is a global term that includes the subchondral bone plate (cortical bone) and the underlying trabecular bone and bone marrow space. An important feature of OA pathophysiology is subchondral bone remodelling. Bone remodelling is characterised by increased subchondral bone thickness (sclerosis), formation of new bone at the joint margins (osteophytes), subchondral bone cyst development and bone marrow lesions (BML) (Henrotin et al, 2009). Interestingly, these abnormalities develop during the final stage of OA and also earlier at the very onset of the disease, maybe even before cartilage degradation (Hilal et al, 1998*; Lajeunesse et al, 1999). Subchondral

bone remodelling is characterised by the accumulation of osteoid substance (sclerosis) and decreased mineralisation related to the production of an abnormal trimeric type I collagen which has a low affinity for calcium (Dequeker et al, 1993; Henrotin et al, 2009). Thus, subchondral bone stiffness is due to an increase in material density, not mineral density (Henrotin et al, 2009). As highlighted above, from a functional and pathophysiological perspective, bone and cartilage are best considered as a biomechanical and biological unit in joint health and disease (Lories and Luyten, 2011).

Figure 4 The bone–cartilage unit is the centre of joint function and disease. The joint enables movement by concerted interaction between its different tissues. Progressive development of osteoarthritis results in activation of different processes and pathways in the distinct tissues and cells of the joint. The current paradigm suggests that these changes evolve simultaneously and that osteoarthritis is not simply a disease of the cartilage or bone. New evidence supports the existence of several types of communication between cartilage and bone. ADAMTS, a disintegrin and metalloproteinase with thrombospondin motifs; MMPs, matrix metalloproteinases; VEGF, vascular endothelial growth factor. 3 Molecular pathogenesis of OA

The pathogenesis of OA should be viewed as a progressive loss of homeostasis within the joint organ involving cartilage, bone, the synovium, ligaments and muscles. Molecular mediators of this process have been extensively studied in cartilage and to a lesser extent in bone and synovium. In chondrocytes, changes occur in extra-cellular matrix synthesis. In addition, the cells start producing proinflammatory cytokines and tissue destructive enzymes. In bone, remodelling and angiogenesis are driven by different types of growth factors. Synovitis is driven by immune cells and proinflammatory cytokines. Systemic factors such as adipokines and sex hormones may also play an active role.

3.1 Changes in cartilage matrix composition and properties

In the early stages of disease, water content is increasing, leading to tissue oedema and weakening of the collagen network. Type II collagen synthesis decreases and is replaced to some extent by type I collagen. Similarly, proteoglycan content strongly decreases and shorter glycosaminoglycans (GAGs) appear. Of note, the concentration of type 6 keratan sulfate increases during the osteoarthritic process to the detriment of type 4 keratan sulfate. These changes modify the capacity of the ECM to retain water, changing the distribution of force in the weight-bearing zone and the transmission of load to the subchondral bone. Of note, some of these effects are also seen in ageing cartilage without strong evidence for the presence of OA. Therefore, a sharp distinction between normal ageing and OA cannot always be made. A prominent feature of ageing cartilage is the accumulation of advanced glycation end products (AGE) leading to protein modification by non-enzymatic glycation. The presence of AGE leads to alteration of biomechanical properties. Moreover, AGE can bind to specific receptors present on the surface of chondrocytes, called receptors of advanced glycation end products (RAGE). The AGE/RAGE system is involved in the catabolic activity of the chondrocytes (Loeser et al, 2005). The loss of proteoglycans may be partially reversible. However, it changes the properties of the ECM, making the collagen structure more susceptible to degradation by collagenases. Importantly, unlike GAGs, the turnover of type II collagen in articular cartilage is very low in adults (Heinemeier et al, 2016). Consequently, damage to the collagen network is generally considered irreversible and may represent the point of no return in joint breakdown.

3.2 Activation of catabolic factors

In OA, the association between matrix-degrading enzymes (including matrix metalloproteinases (MMPs) and aggrecanases) and cartilage damage has been well established (Goldring and Goldring, 2007*). ADAMTS (a disintegrin and metalloproteinase with thrombospondin motifs) are matrix degrading enzymes, and a family of peptidases. In particular, aggrecanase 1 (or ADAMTS-4) and aggrecanase 2 (or ADAMTS-5, which is the same as ADAMTS-11) play a major role in the cleavage of aggrecan (figure 5) (Fosang and Little, 2008; Fosang and Rogerson, 2010).

MMPs are zinc-dependant endopeptidases and belong to the family of proteases known as the metzincin super-family. They are capable of degrading all kinds of ECM proteins. Because they are active at neutral pH, the MMPs can act on the cartilaginous matrix at some distance from the chondrocytes. MMPs can be synthesised by chondrocytes, synoviocytes and osteoblasts, mostly after stimulation by cytokines or mechanical stress.

OA chondrocytes produce a variety of matrix-degrading enzymes including MMP-1, MMP-3, MMP-9, MMP-13, MMP-14 and aggrecanases ADAMTS-4 and ADAMTS-5, thus demonstrating that cartilage cells contribute to the degradation of their own tissue (Cawston and Young, 2010). The activity of MMPs is regulated by serine

proteases (plasminogen activator, plasminogen, plasmin), free radicals, cathepsins and some membrane-type MMPs. Their effect is further controlled by natural inhibitors including the tissue inhibitors of metalloproteinases (TIMPs) by stoichiometric inhibition and the inhibitor of plasminogen activator. Therefore, the balance between the amounts of MMPs and TIMPs in the cartilage determines the level of degradation (Cawston and Young, 2010). Oxygen tension may also regulate MMP13 activity, since hypoxia has been shown to prevent MMP13 expression in chondrocytes and OA-like cartilage catabolism (Bouaziz et al, 2016).

Figure 5 Aggrecanase activity. (A) The aggrecan aggregate comprises numerous aggrecan monomers bound to HA (green) and LP (blue) to form stable trimeric complexes. The aggrecan core protein contains globular G1, G2 and G3 domains, with chondroitin sulfate and keratan sulfate glycosaminoglycans substituted between the G2 and G3 domains. (B) The aggrecanases, ADAMTS-4 and ADAMTS-5, cleave the aggrecan core protein at specific sites. The most detrimental cleavage site is in the IGD between the G1 and G2 domains. Cleavage in the IGD releases the bulk of the monomer from its HA anchor. Other known ADAMTS cleavage sites in the chondroitin sulfate-rich region are not shown. ADAMTS, a disintegrin and metalloproteinase with thrombospondin motifs; HA, hyaluronan; IGD, interglobular domain; LP, link protein. (Reproduced with permission from Fosang and Little, *Nat Clin Pract Rheumatol* 2008;4:420–7.)

Breakdown of type II collagen is mainly due to collagenase-1 (MMP-1) and collagenase-3 (MMP-13). Their expressions differ in term of proteolytic potency, target sensitivity, expression and localisation. Likewise, their respective actions are dependent on the stage of OA. Within the OA cartilage, collagenase-1 is localised in the superficial zone, whereas collagenase-3 is in the deep zone. MMP-13-specific type II collagen cleavage products have been immunolocalised in OA cartilage with cytokines and their receptors (Goldring and Otero, 2011). Stromelysin-1 (MMP-3), Stromelysin-2 (MMP-10) and Stromelysin-3 (MMP-11) are also involved in the degradation of cartilage. Their substrates are proteoglycans, fibronectin, elastin, laminin and type IX collagen (Okada et al, 1992). Matrisylin (MMP-7) is over-expressed in OA cartilage and may play an important role in the degradation of various ECM components such as proteoglycans (Ohta et al, 1998). In rapid destructive hip OA, MMP-3 and MMP-9 are preferentially elevated in synovial fluid and plasma (Masuhara et al, 2002).

3.3 Activation of developmental pathways

Different molecular cascades well-known for their roles in skeletal development are also active in the healthy and osteoarthritic joint. Pathways of particular interest include the transforming growth factor- β (TGF β) family, bone morphogenetic proteins (BMPs) and the Wnt signalling cascade. Although initially considered potential strategies to induce cartilage repair, it has become clear that their effects on joint homeostasis and disease are more complex than anticipated. TGF β is considered an anabolic factor for cartilage. Despite its physiological role in healthy cartilage, the pathway and its downstream effects appear dysregulated in OA (van der Kraan, 2017). In aging cartilage, there appears to be a critical shift in TGF β –receptor interaction, with preferential activation of the activin-like kinase (ALK)-1 receptor over the ALK5 receptor. This process stimulates chondrocyte hypertrophy. In addition, excess production of TGF β also contributes to osteophyte formation and synovial fibrosis (figure 6). A similar view has been developed regarding BMP signalling. BMPs have chondroprotective and stimulating properties but within a specific context may also lead to further differentiation of chondrocytes (hypertrophy) and stimulate osteophyte formation (van der Kraan et al, 2010; Lories, 2011).

The potential role of Wnt signalling, a complex cascade with critical roles in development, growth, homeostasis and disease, appears even more complex (Lories et al, 2013). Cartilage and bone homeostasis require finely tuned Wnt signalling; both activation and suppression of the Wnt– β -catenin cascade can lead to OA in rodent models. Genetic associations and functional studies of the Wnt antagonist encoded by FRZB and the transcriptional regulator encoded by DOT1L (see below) with OA further corroborate the essential part played by Wnts in the joint (Thysen et al, 2015; Monteagudo et al, 2017). Wnts also have a role in the terminal differentiation of chondrocytes, a deleterious outcome in the context of OA.

Therefore, different OA models with genetic-based de-repression of Wnt signalling in vivo demonstrate more severe disease compared with wild-type controls. On the other hand, a complete absence of canonical Wnt signalling also has adverse effects, as survival of cells within cartilage seems to be impaired (figure 7). This suggests that balanced control of Wnt signalling in articular cartilage is required for joint homeostasis.

Figure 6 Transforming growth factor- β (TGF β) plays a role in key characteristics of osteoarthritis (OA): cartilage damage, osteophyte formation and synovial fibrosis. TGF β is required for the maintenance of healthy cartilage during which it signals primarily via Smad2/3. With age and OA, a shift in the activin receptor-like kinase 5 (ALK5):ALK1 ratio is established, favouring Smad1/5/8 signalling and leading to a loss of the cartilage-protective role of Smad2/3. A role is suggested for this balance shift towards ALK1 in cartilage damage during OA development. In addition, TGF β is a crucial factor in the onset of osteophyte development. In later stages of osteophyte development, bone morphogenetic proteins (BMP) might be equally important. TGF β is a major player in fibrotic diseases and, during OA, it induces synovial fibrosis. (Reproduced with permission from van der Kraan et al, Cell Tissue Res 2012;347:257–65.)

Figure 7 The complex roles of Wnts in cartilage homeostasis and disease. (A) Both overexpression and loss of β -catenin in the articular cartilage lead to joint damage. Overexpression of β -catenin results in chondrocyte hypertrophy and loss of matrix quality, whereas loss of β -catenin function results in tissue damage through chondrocyte death. (B) Canonical and non-canonical Wnt signalling pathways keep each other in check through reciprocal inhibition. The canonical pathway appears to stimulate proliferation. The non-canonical pathway stimulates dedifferentiation. (Reproduced with permission from Lories et al, *Nat Rev Rheumatol* 2013;9:328–39.)

3.4 Synovitis and low-grade inflammation

Low-grade inflammation is an important feature of OA pathogenesis. In particular, synovial inflammation plays an important and increasingly recognised role in OA. Cartilage breakdown products released into the joint space increase synovial inflammation. In turn, the inflamed synovium produces catabolic and proinflammatory mediators that lead to excess production of proteolytic enzymes responsible for cartilage breakdown, creating a positive feedback loop (figure 8). The macroscopic distribution of inflammation in OA synovium is patchy and may be confined to areas adjacent to the site of chondropathy (Ayril et al, 2005). The most common histological feature of inflammation of synovial tissue is hyperplasia, with an increased number of lining cells and a mixed cellular infiltrate (Myers et al, 1990; Smith et al, 1997; Mathiessen and Conaghan, 2017). Macrophages and T cells are the most common cells in OA synovial tissue (Sellam and Berenbaum, 2010*), although there is little evidence of a fully developed adaptive immune response. Inflammatory cells and their cytokines are present in both early and late OA (Benito et al, 2005).

Figure 8 Products of cartilage breakdown that are released into the synovial fluid are phagocytosed by synovial cells, increasing synovial inflammation. In turn, activated synovial cells in the inflamed synovium produce catabolic and proinflammatory mediators that lead to excess production of the proteolytic enzymes responsible for cartilage breakdown, creating a positive feedback loop. The inflammatory response is amplified by activated synovial T cells, B cells and infiltrating macrophages. To counteract this inflammatory response, the synovium and cartilage may produce anti-inflammatory cytokines. In addition to these effects on cartilage inflammation and breakdown, the inflamed synovium contributes to the formation of osteophytes via BMPs. ADAMTS, a disintegrin and metalloproteinase with thrombospondin motifs; BMP, bone morphogenetic protein; CXCL13, CXC-chemokine ligand 13; EGF, endothelial growth factor; IL, interleukin; IL-1Ra, IL-1 receptor antagonist; LTB4, leukotriene B4; MMP, matrix metalloproteinase; NAMPT, nicotinamide phosphoribosyl transferase (also called visfatin); NO, nitric oxide; OA, osteoarthritis; PGE2, prostaglandin E2; TIMP, tissue inhibitor of metalloproteinase; TNF, tumour necrosis factor; VCAM-1, vascular cell adhesion molecule 1; VEGF, vascular endothelial growth factor. (Reproduced with permission from Sellam and Berenbaum, *Nat Rev Rheumatol* 2010;6:625–35*.)

Why the synovium becomes inflamed in OA remains unclear. A common hypothesis states that, once degraded, cartilage fragments fall into the joint and contact the synovium. As the cartilage fragments are considered foreign bodies, synovial cells react by producing inflammatory mediators. Another theory considers synovial tissue to be a primary trigger of the OA process. Indeed, many cell types usually present in immunological processes have been described in OA as bystanders and as actors (Berenbaum, 2013). In addition, different triggers of the innate immune system may be active early in the disease process in OA. These triggers include matrix molecules, but also complement and crystals. Additional data point towards a role for systemic inflammation. In other words, inflammatory events occurring within joint tissues could be reflected outside the joint in the plasma and peripheral blood leucocytes of patients with OA. A provocative hypothesis therefore states that OA could be initiated and/or aggravated by the presence of a systemic low-grade inflammation and also that OA could be at the initiation of distant age-related diseases via joint release of inflammatory mediators into the blood stream.

Of note, the infra-patellar fat pad (IFP) may be a specific tissue associated with inflammation and knee OA (Ioan-Facsinay and Kloppenburg, 2013; Eymard et al, 2014). The IFP is a source of several soluble factors. It is composed of adipocytes and stromal vascular cells, such as macrophages, T cells and mesenchymal stem cells. Cellular interactions have been described within the IFP, such as between adipocytes and macrophages or T cells but also between IFP and other joint tissues. Moreover, some differences between the adipose tissue from IFP and the one from synovium have been reported, supporting a specific role for IFP in OA (Harasymowicz et al, 2017).

Both synovium and IFP represent important sources of pro-inflammatory mediators in OA. In addition, chondrocytes and subchondral bone cells are also able to produce cytokines or chemokines upon different types of stimuli, such as mechanical stress. Pro-inflammatory cytokines such as IL-1 β , TNF α or IL-6 are key mediators for the cartilage catabolic process. Chondrocytes have the capacity to produce these cytokines themselves and respond to them by acting via autocrine/paracrine pathways (Robinson et al, 2016). Abnormal mechanical forces and inflammatory mediators can also activate chondrocyte catabolism in a synergistic manner (Kurz et al, 2005). In OA joints, pro-inflammatory cytokines are synthesized in concentrations that are capable of inducing the expression and activation of MMPs, aggrecanases and other catabolic genes. IL-1 is co-localised with TNF α , MMP-1, MMP-3, MMP-8, MMP-13 and type II collagen cleavage epitopes in OA cartilage. Furthermore, IL-1 appears to induce ADAMTS-4, whereas TNF α and IL-6 induce both ADAMTS-4 and ADAMTS-5. Both IL-1 and TNF α increase the synthesis of prostaglandin E2 (PGE2) by stimulating the gene expression and/or the activity of COX-2, microsomal PGE synthetase-1 (mPGES-1) and soluble phospholipase A2 (sPLA2). They also increase the amount of nitric oxide via inducible nitric oxide synthetase (iNOS or NOS2) and induce production of other cytokines, such as the proinflammatory cytokines IL-6, LIF (leucocyte inhibiting factor), IL-17 and IL-18, and also of chemokines such as IL-8. Finally, IL-1 and TNF α suppress a number of genes associated with the differentiated chondrocyte phenotype, including aggrecan (AGAN) and type II collagen (COL2A1) (Goldring and Otero, 2011).

Chemokines (such as IL-8, CCL2, CCL5, CCL19) and their receptors (such as CCR1, CCR2, CCR3 and CCR5) are also important inflammatory mediators during OA. In particular, data from animal models indicate that CCL2/CCR2 signaling might be involved in OA-related pain and in the accumulation of macrophages in OA synovium. However, the role of CCR2 in cartilage degradation is still a matter of debate (Miller and Malfait, 2017).

3.5 Systemic mediators

Chondrocytes bear oestrogen receptors and their stimulation can trigger the production of growth factors. The concentration of oestrogens decreases during menopause, leading to a decrease in the synthesis of these growth factors. Obesity is a risk factor for OA for both weight-bearing joints and also for non-weight-bearing joints such as the hands, suggesting a role for the adipose tissue which secretes many soluble mediators. Among them, adipocytokines (or adipokines) have been described as mediators of inflammation. Moreover, these adipokines are not restricted to the adipose tissue and could also be secreted by other tissue. It has been shown that adipokines (resistin, leptin and adiponectin) are found in synovial fluid (Schaffler et al, 2003) and have multiple functions (table 1).

Table 1 The role of adipocytokines in the pathogenesis of osteoarthritis (Adapted from Lago et al, *Nat Clin Pract Rheumatol* 2007;3:716–24 and Gosset et al, *Arthritis Rheum* 2008;58:1399–409)

	Observations
Leptin	Leptin expression in cartilage is positively associated with the severity of OA ↑ NO (synergy with IFN-γ and IL-1) ↑ MMPs 9–13 ↑ IGF-1, ↑ TGFβ ↑ Synovial concentration versus serum concentration?
Adiponectin	↑ IL-6 and ↑ MMP-1 by synovial fibroblasts ↓ Synovial concentration versus serum concentration
Visfatin	Produced by human chondrocytes Increased expression by IL-1 stimulation ↑ PGE2, ADAMTS-4, ADAMTS-5, MMP-63, MMP-13
Resistin	Induces osteoarthritis when injected into mouse knee joints

ADAMTS, a disintegrin and metalloproteinase with thrombospondin motifs; IL, interleukin; MMP, matrix metalloproteinase; NO, nitric oxide; OA, osteoarthritis; PGE2, prostaglandin E2.

Thus, OA may be related to the metabolic syndrome. In this context, at least some patients may develop OA as a consequence of metabolic abnormalities. For instance, studies have demonstrated associations linking OA to several components of the metabolic syndrome, such as hypertension and type 2 diabetes (Eymard et al, 2015; Courties et al, 2017). However, it should be underlined that body mass index (BMI) represent a potential confounder in these epidemiological associations with knee OA (Niu et al, 2017). Preclinical findings indicate a deleterious effect of lipid and glucose abnormalities on cartilage homeostasis. Chronic low-grade inflammation, as highlighted above, is a feature shared by OA and metabolic disorders and may contribute to the genesis of both. Thus, OA is emerging as a disease that has a variety of phenotypes including a metabolic phenotype, in addition to the age-related and injury-related phenotypes.

4 Epidemiology and risk factors

4.1 Prevalence of OA

The prevalence of OA depends on the precise definition used. For example, the classification criteria of the American College of Rheumatology have been rarely used in epidemiological studies. One limitation of

epidemiological studies concerning OA is that individuals differ in their threshold for reporting pain. Furthermore, other conditions such as bursitis, tendonitis or fibromyalgia may mimic OA pain. Definitions of OA differ and cross-sectional studies have the limitation that individuals without OA at a given time-point, may have become patients a few years later.

Autopsies can be a way to investigate OA prevalence. These studies have shown that degenerative joint changes begin in the second decade (Lowman, 1955). This result corroborates the fact that radiological OA is more prevalent than symptomatic OA (Kelsey and Hochberg, 1988).

The occurrence of OA differs according to geographical area and country, since these are associated with variation in risks, genetics and environmental factors. For example, congenital acetabular hip dysplasia increases the risk of hip OA, while squatting predisposes to knee OA but protects against hip OA. Thus, interpretation of epidemiological studies on OA should take into account their geographical origin (Cimmino and Parodi, 2005).

The knee is the most clinically significant site affected by OA. The age- and sex-standardised incidence of knee OA is 240/100 000 person-years. The incidence of hand OA is 100/100 000 person-years, while for hip OA it is 88/100 000 person-years (Oliveria et al, 1995). Hand, hip and knee OA become more frequent with age, and more women are affected than men after age 50.

Gender plays a role in both radiographic and symptomatic OA. The prevalence of knee OA is higher in women than in men, while hip OA seems more frequent in men (Kellgren and Lawrence, 1958). Hand OA is more frequent in women (van Saase et al, 1989). In patients above 70 years of age, the prevalence of radiographic hand OA is 90% in women and 80% in men. Interestingly, female hand OA risk is greatest around the menopause, suggesting a role for systemic hormonal factors in the onset of the disease (Prieto-Alhambra et al, 2014).

In the USA, the number of people with clinical OA has increased to nearly 27 million, up from an estimate for 1995 of 21 million, as would be expected for such a strongly age-related disease (Lawrence et al, 2008*).

4.2 Natural history of OA

Primary OA is a chronic disorder but its natural history can vary greatly. OA generally develops progressively over several years, although symptoms may remain relatively stable for prolonged periods. Previous trauma, causing articular, meniscal or ligament damage or joint incongruity, can reveal or accelerate OA progression and symptom appearance and deterioration, especially in knee OA. Prodromal symptoms may occur and worsen in the years preceding the first diagnosis of radiographic OA, and in most cases, remain stable afterwards (Whittle et al, 2016). The correlation between clinical outcome and the radiographic course of disease is relatively poor at the individual level. Thus, whereas symptoms can improve, the radiographic

picture rarely does (Duncan et al, 2011). Prospective studies indicate that only a small subset of knees with OA will show radiographic progression in the following year, whereas most patients will remain stable (Felson et al, 2013).

Although OA is considered to be a chronic degenerative process, flares can occur during the course of the disease. Inflammatory arthritis, infection and crystal arthropathies should be excluded in such cases. Flares do not have a consensual definition but are characterised by sudden episodes of increased pain (possibly nocturnal), with morning stiffness and the development of synovial effusions or synovitis. Joint deterioration is especially seen with increasing age. Furthermore, knee deterioration is associated with obesity, varus malalignment, the presence of OA in other joints and radiographic features (Chapple et al, 2011). Hip deterioration is associated with radiographic features such as femoral head migration, femoral osteophytes and joint space narrowing, and pain and disability (Wright et al, 2009). Occasionally there may be rapid destruction of joints, which is associated with a poor prognosis. Regional localisation of destruction is classified into discrete clinical syndromes including those affecting the hip ('rapid destructive hip arthropathy'), the shoulder ('Milwaukee shoulder'), the spine ('pseudotuberculosis spondylodiscitis') and the knee.

4.3 Predisposing factors

A causal risk factor must fulfil several criteria, including a time relationship, a strong statistical association after exclusion of confounding factors, consistent published findings and biological plausibility. The predisposing risk factors for idiopathic OA act by increasing the susceptibility of joints to injury, by direct damage to joints, or by impairing the process of repair of damaged joint tissue. OA can develop in a normal joint through excessive injury or in a primarily altered joint (i.e., dysplasia, genu varum) by normal physical stress. Table 2 shows some of the main risk factors identified to date (Cimmino and Parodi, 2005). We must differentiate between factors for occurrence and factors for progression. Clinicians should also distinguish 'not modifiable' risk factors, which are valuable from a pathophysiological point of view and in groups, and 'modifiable' factors, which are potentially more valuable for individuals in routine practice.

Table 2 Risk factors for the occurrence or progression of osteoarthritis (OA) in the knees, hips and hands

	Location		
	Knee	Hip	Hand
Occurrence of OA	Age	Age	Age
	Female	Ethnicity	Female
	Ethnicity	Physical activity	Ethnicity
	Physical activity	Body Mass Index	Grip strength
	Body Mass Index	Previous injury	Body Mass Index
	Bone density	Intense sport activities	Occupation
	Previous injury	Occupation	Intense sport activities
	Smoking (protective)		
	Alignment		
	Quadriceps strength		
	Intense sport activities		
Progression of OA	Age	Age	Unknown
	Bone density	Symptomatic activity	
	Alignment	Gender	
	Hyarthrodial OA	Intense sport activities	
	Synovitis		
	Intense sport activities		
	Subchondral bone oedema on MRI		

4.4 Obesity and metabolic disorder

Obesity, the main modifiable risk factor for OA, seems to be independently implicated in the pathogenesis of OA. It is among the strongest risk factor for knee OA, especially in the case of bilateral knee involvement and in OA in women (Felson, 1996; Cimmino and Parodi, 2005). Obese patients also have a higher risk of bilateral hip OA but to a lesser extent than for the knee (Tepper and Hochberg, 1993). Obesity is associated with OA in weight-bearing joints, possibly due to cartilage breakdown upon abnormal loading, but also with OA in non-weight-bearing joints, such as the hand. This shows that obesity is a real systemic risk factor for OA (Pottie et al, 2006). The link between obesity and OA is stronger in women than in men.

Two mechanisms can explain the role of obesity in OA development. First, obesity increases mechanical stress on weight-bearing joints. Moreover, obese patients have a higher bone mass, which may increase stiffness in the subchondral bone and facilitate cartilage breakdown. Second, several proteins that are over-expressed in obesity are also involved in OA development, such as cytokines or adipokines like visfatin, explaining the putative effect of obesity on non-weight-bearing joints (Gosset et al, 2008; Courties et al, 2017).

Other metabolic disorders, such as hyperglycaemia, have also been associated with OA occurrence and severity, probably through changes in matrix macromolecules (Cimmino and Parodi, 2005). Diabetes was

associated with risk for bilateral knee OA and hypercholesterolemia was independently associated with generalised OA (Felson, 1996; Sturmer et al, 2001). This has been incorporated in the hypothesis that at least a subset of OA patients actually have metabolic OA (Courties et al, 2017).

4.5 Dietary intake and nutriment

Some studies have shown that the antioxidants, some carotenoids and vitamin C are associated with lower progression or lower incidence of OA (McAlindon et al, 1996a; Seki et al, 2010). However, their effect is not very strong and there is no convincing evidence that supplementation will be beneficial for individual patients. Dietary fibre, which may help to reduce body weight and have a protective effect on several metabolic disorders and systemic inflammation, might also decrease the risk of symptomatic knee OA, but not radiographic knee OA (Dai et al, 2017). The impact of vitamin D deficiency on OA have been extensively studied, and results are controversial. Overall, there is only a weak association between low levels of vitamin D and knee OA, but not with hip or hand OA (Bergink et al, 2016), and most randomized controlled trials investigating vitamin D supplementation in knee OA are negative (McAlindon et al, 2013).

4.6 Age, sex and ethnicity

Patient age is the best recognised risk factor, since the incidence of radiographic and symptomatic OA increases sharply with age. This is probably mediated by increases in systemic and local factors, including obesity, ligament laxity, and impaired neuromuscular joint-protective mechanisms. A systemic pro-inflammatory state promoted by aging called “inflamm-aging” may also contribute to age-related OA pathogenesis (Greene and Loeser, 2015).

Women are at greater risk than men of developing hand, knee and generalised OA (Dougados et al, 1996*; Jonsson et al, 2003; Arden and Nevitt, 2006*). In contrast, the frequency of hip OA increases at about the same rate in women and men, but the disease seems to progress more rapidly in women (Kellgren and Lawrence, 1958; Botha-Scheepers et al, 2008). On the same line, radiographic lesions are more severe in women than men after 55 years (Srikanth et al, 2005).

The prevalence of OA in different ethnic groups and races has been extensively studied. In the USA, knee OA is more common and more severe in the African-American population than in the Caucasian population (Dillon et al, 2006; Braga et al, 2009). The prevalence of knee OA seems to be similar between Chinese and Caucasian men of the same age, while Chinese women had a significantly higher prevalence of knee OA (Zhang et al, 2001). Both hip and hand OA are less common among the Chinese population than among the US Caucasian population (Nevitt et al, 2002; Zhang et al, 2003).

4.7 Bone density

A link between bone mineral density (BMD) and the occurrence of OA has been reported, but the mechanism requires further elucidation. According to epidemiological studies, radiographic hip OA seems to be associated with higher BMD (Nevitt et al, 1995; Stewart et al, 1999; Lane and Nevitt, 2002). The prevalence of radiographic knee OA also increases with increasing BMD (Lane and Nevitt, 2002). Prospective studies have shown that high BMD or an increase in BMD increases the incidence of new radiographic knee OA (Zhang et al, 2000; Hart et al, 2002). At the same time, high BMD and an increase in BMD may also decrease the risk of progression of knee OA (Zhang et al, 2000). The relationship between BMD and OA has been controversial for decades. An inverse relationship between osteoporosis and OA has been extensively supported but also challenged (Dequeker et al, 2003). A recent review of the literature provides detailed insights: OA is inversely related to osteoporosis in general when studied cross-sectionally and systematically. However, when analysed in individual bones, the BMD of the appendicular skeleton in OA-affected joints may decrease, particularly in the upper extremities. Low BMD at the lumbar spine is associated with a lower incidence of knee OA does not impact the progression of knee OA (Im and Kim, 2014).

4.8 Sex hormones

Sex hormones seem to be involved in OA pathogenesis since the prevalence and incidence of OA is higher in women than in men, especially around the menopause (Richette et al, 2003; Prieto-Alhambra et al, 2014). This can be explained by the presence of oestrogen receptors in chondrocytes and modulation of their function depending on sex hormones (Richette et al, 2007). Numerous animal studies found that ovariectomy resulted in cartilage damage (Sniekers et al, 2008). However, the association between OA and hormone replacement therapy is unclear (de Klerk et al, 2009).

4.9 Occupational factors

The occurrence of OA is associated with particular physical activity during work, for instance laying floors and carpentry is associated with knee OA (Rytter et al, 2009). Frequent climbing of stairs can favour hip and knee OA (Lau et al, 2000). Hip OA seems also favoured by occupational activities such as farming, prolonged standing, weight lifting and walking over rough ground (Croft et al, 1992a). On the other hand, more active individuals may have a reduction in risk of knee OA from avoiding weight gain than those less active (Martin et al, 2013).

Hand use may have a protective effect on finger joint OA, whereas continuous joint overload may lead to joint impairment (Solovieva et al, 2005). The pattern of work task history is associated with its localisation (Solovieva et al, 2006). Carpo-metacarpal OA of the thumb mainly occurs in occupations involving repetitive

thumb use such as tailoring and dressmaking, while severe OA of the right thumb, index and middle fingers occurs in dentists (Solovieva et al, 2005; Fontana et al, 2007).

4.10 Joint deformity and laxity

Joint deformity is associated with the development of OA. Congenital abnormal joint shapes, such as acetabular dysplasia, slipped capital femoral epiphysis, abnormal femoral head shape or abnormal femoral neck shaft angle of the hip, can be considered as aetiologies of secondary OA. They act by disturbing the load distribution within the joint (Harris, 1986; Lane et al, 2000; Doherty et al, 2008). Angular misalignment increases the degree of focal loading, creating a vicious cycle of joint damage, contributing to the development and progression of single compartment OA of the knee. About 65% of the weight-bearing load is transmitted through the medial compartment in a normally aligned knee, which explains the greater frequency of tibiofemoral medial knee OA (Andriacchi, 1994). Globally, varus misalignment increases the risk of joint space narrowing three- to fourfold (Sharma et al, 2001). Valgus malalignment also increases the risk of knee OA incidence and radiographic progression, possibly by increasing the risk of meniscal damage (Felson et al, 2013).

Obesity and misalignment act in combination to increase the risk of structural radiographic progression. Longstanding obesity seems to increase the risk of structural radiographic progression in cases of moderate misalignment, presumably due to the combined effect of the focus of load from misalignment and the excess load from increased weight (Felson et al, 2004; Runhaar et al, 2014).

Joint laxity, responsible for malalignment, may be a further accelerating factor for OA.

4.11 Acute injury and repetitive joint loading

It has been estimated that approximately 12% of symptomatic OA is attributable to post-traumatic OA of the hip, knee, or ankle (Brown et al, 2006). Fractures of the limbs are potential causes of secondary OA (Volpin et al, 1990; Honkonen et al, 1995). For instance, intra-articular fractures may increase the risk of subsequent OA more than 20-fold (Anderson et al, 2011). The pathomechanisms linking these fractures to cartilage destruction are poorly understood, although secondary load changes on the joint play a role. Furthermore, a link has been made between injury and chondrocyte death (McKinley et al, 2010).

Previous hip and knee injuries are independent risk factors for OA according to several epidemiological studies (Cooper et al, 1998; Gelber et al, 2000).

Acute joint injuries, especially anterior cruciate ligament (ACL) damage or tears of the meniscus, are clearly associated with knee OA and its progression (Roos et al, 1998b; Sowers et al, 1999; Cooper et al, 2000; Gelber et al, 2000; Englund et al, 2004). There is a combined effect of the injury itself and its biomechanical consequences which alter load distribution on the joint. Capsular or ligamentous injury can increase the risk of

subsequent OA by 10-fold (Anderson et al, 2011). Unfortunately, the development and progression of OA may still occur even if the damaged anterior cruciate ligament is surgically repaired, especially in patients with anterior laxity or combined injuries (Oiestad et al, 2010; Struwer et al, 2011). OA often presents as a slight reduction of joint space about 10–20 years after anterior cruciate ligament injury, but usually without any major clinical symptoms (Gillquist and Messner, 1999).

Meniscus damage may play an important role in OA pathophysiology (Hunter, 2009). However, whether meniscus damage or cartilage degradation occurs first is still unknown. It seems clear that a torn meniscus and extrusion are strong risk factors for the development and progression of knee OA. Meniscectomy increases the risk of knee OA twofold and even more if it is combined with ligament injury. There is a significant risk of radiographic tibiofemoral and patella-femoral OA 20 years after the surgical removal of a meniscus following knee injury, with the relative risk estimated to be 14 (Roos et al, 1998a; Englund and Lohmander, 2005). Moreover, obesity enhances the effect of meniscal damage. Partial meniscus resection seems to have less impact than total meniscectomy (Englund and Lohmander, 2004).

The mechanisms leading to OA following joint injury are poorly known, but inflammation is likely to play an important role in this process. Several inflammatory mediators such as IL-6 or CCL2 are released into synovial fluid early after knee joint injury (Watt et al, 2016). Interestingly, IL-6 levels in synovial fluid are also associated with progression of radiographic knee OA in patients with history of meniscectomy (Larsson et al, 2015). On the same line, the pivotal role of IL-6 in post-traumatic OA has been pointed out in preclinical studies (Nasi et al, 2016; Latourte et al, 2017). However, the exact contribution of inflammatory mediators in the pathogenesis of posttraumatic OA remains to be further elucidated (Lieberthal et al, 2015).

Repetitive activities with joint overuse increase the risk of developing OA, particularly in the knee, hip and distal interphalangeal joints. Obesity amplifies this effect on the knee (Felson et al, 1991; Coggon et al, 2000). Professional and elite sporting activities are also associated with the development of OA, even without major injury: for example, marathon athletes may suffer from hip OA (Buckwalter and Lane, 1997) and professional soccer players from knee OA. However, reasonable sports during leisure time, such as recreational running, are not likely to be harmful for most individuals in terms of the occurrence or progression of hip and knee OA in the absence of sudden impacts, previous injury, meniscectomy or joint dysplasia (Cimmino and Parodi, 2005; Lo et al, 2017).

Furthermore, walking in high-heeled shoes may predispose to degenerative changes in the patellofemoral and medial compartments of the knee (Kerrigan, 2005), but the direct association with OA remains inconclusive (Barnish and Barnish, 2016).

4.12 Muscle weakness

Quadriceps weakness has been described as a risk factor for knee pain, disability and progression of knee OA (Slemenda et al, 1997). However, data about the effect of quadriceps strength on OA development and progression are conflicting. While quadriceps weakness has been associated with the development of radiographic knee OA, quadriceps muscle strength is also associated with faster progression in deformed knees (Arden and Nevitt, 2006*). Lower-limb muscles, particularly the quadriceps, influence knee joint load, a major contributor to knee OA. Impairments in muscle function including weakness, altered activation patterns and proprioceptive deficits are commonly found in association with knee OA. Furthermore, there is some evidence that muscle weakness may predispose to the onset and potentially the progression of knee OA. For instance, a lower thigh muscle strength might predict the risk of total knee replacement in women (Culvenor et al, 2016). Several studies indicate that muscle strength might be associated to knee pain or function but not to radiographic outcomes (van der Esch et al, 2014; Muraki et al, 2015). Exercise is a key component of conservative management of knee OA and has been found to be effective in symptom reduction (Bennell et al, 2014). Whether exercise influences disease development and progression requires further research, especially given the contradictory data. As in many other examples regarding OA, specific subtypes and patient characteristics are likely to influence individual treatment decisions. Moreover, muscle power might be more important than muscle strength to investigate this association in patients with OA (Reid et al, 2015).

4.13 Genetic and epigenetic factors

OA has a complex aetiology to which genetic factors also contribute (Reynard and Loughlin, 2013). Evidence of a genetic influence on OA comes from a number of sources, including epidemiological studies, linkage studies, candidate gene approaches and genome-wide association studies (GWAS). Discovery of genetic susceptibility factors associated with OA has been hindered by the different phenotypical manifestations, and the difficulty of selecting an appropriate definition of disease, thereby clearly discriminating patients and controls in view of the progressive nature of the disease (Kerkhof et al, 2011). Candidate gene approaches, once very popular, had power issues and suggested associations rarely replicated in other populations. Novel technologies, in particular GWAS, and meta-analyses on large datasets and multiple cohorts have been welcomed but mainly identified regions with multiple candidate genes (Kerkhof et al, 2010; Zeggini et al, 2012; Evangelou et al, 2013; Rodriguez-Fontenla et al, 2014; Styrkarsdottir et al, 2014). Often these regions have a number of potential candidate genes but for many, insights into their role in joint biology is lacking. A list of loci of strong interest is found in table 3. Ultimately, genetic studies can lead to unravelling of molecular mechanisms involved in OA development and progression. These mechanisms can be potential targets for treatment. Ideally, identification of genetic risk factors for OA can be used to recognise subjects at risk for OA onset or progression.

Table 3 (Possible) genes of interest in osteoarthritis

SNP (chromosomal location)	Genes implicated	Protein	Protein function
rs6976 (3p21.1)	<i>STAB1</i>	Stabilin-1	Transmembrane receptor
	<i>NT5DC2</i>	5'-Nucleotidase domain-containing protein 2	Unknown
	<i>PBRM1</i>	Polybromo-1	Transcriptional activation
	<i>GNL3</i>	Guanine nucleotide-binding protein-like 3	Stem cell proliferation
	<i>GLT8D1</i>	Glycosyltransferase 8 domain-containing protein 1	Glycosyltransferase
	<i>SPCS1</i>	Signal peptidase complex subunit 1	Unknown
	<i>NEK4</i>	Serine/threonine-protein kinase Nek4	Kinase
	<i>ITIH1</i>	Inter-alpha-trypsin inhibitor heavy chain H1	Serine protease inhibitor
	<i>ITIH3</i>	Inter-alpha-trypsin inhibitor heavy chain H3	Serine protease inhibitor
	<i>ITIH4</i>	Inter-alpha-trypsin inhibitor heavy chain H4	Serine protease inhibitor
	<i>MUSTN1</i>	Musculoskeletal embryonic nuclear protein 1	Nuclear protein
	<i>TMEM110</i>	Transmembrane protein 110	Unknown
rs12107036† (3q28)	<i>TP63</i>	Tumour protein 63	Transcription factor
rs10948172† (6p21.1)	<i>SUPT3H</i>	Transcription initiation protein SPT3 homologue	Unknown
	<i>RUNX2</i>	Runt-related transcription factor 2	Transcription factor
rs9350591 (6q13–q14.1)	<i>COL12A1</i>	Collagen α1(XII) chain	FACIT collagen
	<i>COX7A2</i>	Mitochondrial cytochrome c oxidase subunit 7A2	Cytochrome C oxidase
	<i>TMEM30A</i>	Cell cycle control protein 50A	Transporter
	<i>FILIP1</i>	Filamin-A-interacting protein 1	Interacts with filamin
	<i>SEN6</i>	Sentrin-specific protease 6	Ubiquitin-like molecule
	<i>MYO6</i>	Unconventional myosin-VI	Vesicle and organelle transport
	<i>IMPG1</i>	Interphotoreceptor matrix proteoglycan 1	Proteoglycan
rs3815148 (7q22)	<i>PRKAR2B</i>	cAMP-dependent protein kinase type IIβ regulatory	cAMP signalling
	<i>HPB1</i>	HMG-box transcription factor 1	Transcription factor
	<i>COG5</i>	Conserved oligomeric Golgi complex subunit 5	Golgi morphology and function
	<i>GPR22</i>	G-protein-coupled receptor 22	Probable G-protein-coupled receptor
	<i>DUS4L</i>	tRNA-dihydrouridine(20a/20b) synthase [NAD(P) ⁺]-like	Unknown

rs4836732 (9q33.1)	BCAP29	B-cell receptor-associated protein 29	Unknown
	PAPPA	Pappalysin-1	Secreted metalloproteinase
	ASTN2	Astrotactin-2	Neural migration
	TRIM32	E3 ubiquitin-protein ligase TRIM32	Protein ubiquitylation
rs10492367 (12p11.22)	KLHDC5	Kelch domain-containing protein 5	Protein ubiquitylation
rs835487 (12q23.3)	PTH1H	Parathyroid hormone-related protein	Hormone
rs11842874 (13q34)11	CHST11	Carbohydrate sulphotransferase 11	Chondroitin sulphation
	MCF2L	Guanine nucleotide exchange factor DBS	Cell movement
rs8044769‡ (16q12.2)3	FTO	α-Ketoglutarate-dependent dioxygenase FTO	Unknown
rs12982744 (19p13.3)77, 78	DOT1L	Histone-lysine N-methyltransferase, H3 lysine-79 specific	Histone and chromatin modifier
rs143383 (20q11.22)12	GDF5	Growth/differentiation factor 5	Extracellular growth factor

Genome-wide association studies and meta-analyses on large datasets and multiple cohorts have identified regions with multiple candidate genes. Often these regions have a number of potential candidate genes but for many, insights into their role in joint biology is (still) lacking.

According to genetic studies in non-consanguineous families, including patients with precocious development of diffuse OA and mild spondylo-epiphyseal dysplasia characterised by genetic Mendelian transmission, polymorphisms of the type II collagen gene (COL2A1) located in chromosome 12 have been implicated in diffuse OA development (Ala-Kokko et al, 1990). However, in large populations this gene does not seem to have a major effect (Baldwin et al, 2002).

From recent genetic studies in primary OA, two pathways may be deduced that are putatively involved in OA aetiology. The first group of genes is involved in the inflammatory pathway: variants in the IL1 gene cluster, the HLA cluster and the cyclooxygenase 2 (COX2) gene (Attur et al, 2010; Moxley et al, 2010; Nakajima et al, 2010; Schneider et al, 2011). Associations with the IL1 gene cluster are shown for knee, hip and hand OA (Loughlin et al, 2002; Meulenbelt et al, 2004; Smith et al, 2004; Moxley et al, 2007; Kanoh et al, 2008; Attur et al, 2010). However, genetic variation at the IL1 gene cluster was associated with lower IL-1 β bio-availability on the one hand and with OA at a large number of joint locations in an individual on the other hand, illustrating the complexity of predisposition through genetic variation (Meulenbelt et al, 2010).

The second group of genes appears to be either involved in early skeletal developmental processes or maintenance of cartilage and bone: growth/differentiation factor 5 (GDF5) (Miyamoto et al, 2007), frizzled-related protein β (FRZB) (Loughlin et al, 2004; Lories et al, 2007; Lories et al, 2009), osteoprotegerin (OPG) (Ramos et al, 2015), transforming growth factor (TGF) β / SMAD3 (Valdes and Spector, 2010*) and type 2 iodothyronine deiodinase (DIO2) (Meulenbelt et al, 2008). These genes are involved in the orchestration of

growth-plate chondrocytes and implicated in the formation of cartilage and endochondral ossification in early skeletal development (Goldring et al, 2006).

The strongest and best reproduced genetic signal is the GDF5 gene. GDF5, also known as cartilage derived morphogenic protein 1 (CDMP1), is a member of the bone morphogenetic protein (BMP)/transforming growth factor (TGF)- β superfamily and was originally identified from a chondrogenic extract of articular cartilage. During joint development it is specifically expressed in the joint interzone, the region in which the prospective joint is formed (Storm and Kingsley, 1996). GDF5 stimulates proliferation and differentiation of chondrocytes. A 5' UTR C/T single nucleotide polymorphism (SNP) (rs143383) has been associated with OA, with the susceptibility variant resulting in lower expression levels (Miyamoto et al, 2007). This association is one of a few genetic variants confirmed in different ethnic groups and by meta-analysis (Evangelou et al, 2009; Valdes and Spector, 2011; Yau et al, 2017). Taking GDF5's chondrogenic properties into account, its potential as a cartilage growth factor is obvious. However, the biology of GDF5 appears much more complex, with effects on different tissues in the joint. Cells expressing GDF5 during embryogenesis may become a subpopulation of synovial cells with stem cells properties, contributing to cartilage repair in case of injury (Roelofs et al, 2017). Intra-articular injections of recombinant GDF5 has protective effects in a rat model of OA (Parrish et al, 2017). Conversely, lack of or a reduction in GDF5 may result in abnormal ligament laxity and thereby contribute to OA development through joint instability (Daans et al, 2011). In addition, GDF5 likely also contributes to subchondral bone modelling and remodelling with reduced GDF5 levels associated with abnormal structure of the collagen network (Daans et al, 2011).

One of the difficulties in genetic studies focusing on OA is the lack of a standardised definition of the OA phenotype, which leads to heterogeneity (Kerkhof et al, 2011). Radiographic or symptomatic findings or the presence of total joint replacement are used to define OA in these studies. However, attempts are being made to introduce more standardisation in future studies. Therefore, alternative 'endpoints' for disease have also been proposed. An example of such an alternative approach is a GWAS that has been performed to identify genes involved in hip joint space width as a proxy for cartilage thickness and OA (Castaño Betancourt et al, 2012). This study identified a genetic variant in the DOT1-like, histone H3 methyltransferase (DOT1L) gene robustly associated with joint space width and hip OA. The DOT1L association is interesting for different reasons. First, DOT1L is an enzyme and can be targeted pharmaceutically (Barry et al, 2010). DOT1L inhibitors are currently in clinical trial in cancer research (Daigle et al, 2011; Deshpande et al, 2012). Second, DOT1L biology links with the Wnt signalling cascade (Mahmoudi et al, 2010; Castaño Betancourt et al, 2012). Third, the DOT1L gene has also been associated with human height (Sovio et al, 2009). This quantitative phenotypical trait has also been linked with other OA susceptibility genes (Sanna et al, 2008), emphasising the likely involvement of growth factors in the disease. Preclinical data have pointed out a critical role for DOT1L in

cartilage health and osteoarthritis by regulating Wnt signalling, thereby opening up interesting therapeutic perspectives (Monteagudo et al, 2017).

DOT1L links to epigenetic regulation of genes. This is defined as heritable changes in DNA without changes in the sequence and could also be involved in the OA process. An example of epigenetic regulation is DNA methylation, as de-methylation can lead to an increase in the gene transcription. Several enzymes involved in cartilage breakdown in OA undergo epigenetic regulation (MMP-3, MMP-9, MMP-13, ADAMTS-4) and also the IL1B promoter region in chondrocytes and leptin which regulates expression of MMP-13 (Roach et al, 2005; Iliopoulos et al, 2007; Hashimoto et al, 2009). The role of epigenetics is currently being studied. The main hypothesis is that growth factors and proinflammatory cytokines regulate the methylation state of pro-degradative agent genes. Ageing and cellular senescence can also participate in changing methylation status (Roach and Aigner, 2007).

A bunch of genome-wide methylation studies have been performed in osteoarthritic cartilage, identifying different methylation profiles in enhancers or promoters of genes involved in embryogenesis and skeletal development, matrix regulation, Wnt pathway, angiogenesis and inflammation (Ramos and Meulenbelt, 2017). The interpretation of these studies is limited by their important variability in terms of study set up, statistical analysis protocols or types of platforms used to measure methylation. Moreover, their cross-sectional design precludes any conclusion on the causal relationship of the epigenetic modifications observed. However, the study of different cartilage regions of tibial plateau representing early, intermediate and late stages of OA suggests that changes in DNA methylation in cartilage occur at the late stages of OA (Zhang et al, 2016). The specific study of subchondral bone might also reveal a particular epigenetic phenotype for this joint tissue during OA (Jeffries et al, 2016). Other epigenetic control mechanisms, such as micro RNAs (miRNAs) or histone modifications, are also under investigation in OA (Ramos and Meulenbelt, 2017).

4.14 Consequence of the identification of a risk factor

Some of the most important risk factors for OA identified to date are ‘non-modifiable’, such as female gender, joint malformation and previous trauma. Knowledge of these factors may help to prevent OA in certain subpopulations.

Prevention and/or treatment of a modifiable risk factor for OA also do not guarantee OA evolution will be influenced. Physical exercise and weight reduction, for example, have both been shown to affect pain and function in knee OA. On the other hand, it is still not clear if modifying footwear is effective, or if muscle strengthening leads to structural progression in patients with misaligned or lax knees (Roddy and Doherty, 2006).

5 Clinical features

5.1 Symptoms of OA

Pain or stiffness in and around one or more joints is the most common reason for patients with OA to seek the advice of a physician. This feature, sometimes together with the clear presence of risk factors in the patient such as age and obesity, should prompt a detailed history and clinical examination. Symptoms are often initially insidious and can be highly variable, depending on the joint affected, the severity and the number of joints affected (Peat et al, 2001*). Involvement of many joints may suggest a systemic form of arthritis (metabolic or inflammatory). Familial history is important, in particular for patients presenting with pain and stiffness in the hands or hip. Imaging, discussed below, can aid in the diagnostic process but frequently there is no correlation between the joint symptoms and the structural alterations on radiographs. However, definitive structural radiographic signs of OA such as joint space narrowing or eburnation on a peripheral joint are associated with the risk of developing related symptoms.

A few general principles should be applied. The rheumatologist should keep in mind that the main challenges in the differential diagnosis of OA are to distinguish OA patients from those with chronic inflammatory disorders and to specifically identify the relatively rare patients with a clear secondary form of OA who have an underlying and often treatable endocrine or metabolic disorder.

Pain is the first and predominant symptom of OA. It typically occurs after joint use and is relieved by rest. With disease progression, pain occurs with minimal motion or even at rest and finally even during sleep. Although OA pain is not usually present at night or at rest, there are exceptions: patients with mild OA using joints for several hours, especially during sport; patients with advanced OA and destructive arthropathy; and patients with an acute inflammatory flare of OA mimicking inflammatory arthropathy, especially regarding erosive hand OA. Because cartilage has no nerve supply and is insensitive to pain, the pain in OA must arise from non-cartilaginous structures such as the periosteum, intra-articular ligaments, pressure on subchondral bone with venous engorgement, intramedullary engorgement, capsular distension, and alterations in synovium or tendons and fascia. Pain may also arise in the presence of an associated bursitis. Peri-articular tissue such as tendons and fascia are also sources of pain during the OA process. Furthermore, central pain processing is altered in patients with OA (Lee et al, 2011). Indeed, central sensitisation, its correlation with structural changes in the joint, and the efficacy of novel analgesics have led to new insights into the pathophysiology of OA pain. This will likely offer new opportunities for targeting and improving the safety of analgesia. In addition, using clinical and genetic approaches, subsets of patients with pain of different pathophysiology could be identified, thus enabling a tailored approach to pain management (Malfait and Schnitzer, 2013). Finally, there is no agreement as to whether a decrease in atmospheric pressure or a change in the weather increases OA

pain, although such an observation is frequently reported by individual patients (Wilder et al, 2003; Verges et al, 2004).

Stiffness may also occur in the morning or after periods of inactivity during the day. Morning stiffness generally resolves after less than 15 min. A so-called ‘gel phenomenon’, defined as stiffness appearing after rest or inactivity, is usually limited to a few minutes.

Limitations of motion and function develop as OA progresses and are related to joint surface incongruity with reduced joint space, muscle spasm or diminished strength leading to instability and mechanical block from osteophytes and loose bodies. Moreover, joint proprioceptor sensitivity may be altered. Patients report limitations in their ability to perform day-to-day activities, like kneeling for knee OA, or cutting one’s toenails for hip OA. OA can also hamper stair climbing, walking and performing household chores. In weight-bearing joints, an abrupt ‘giving way’ may occur. In hand OA, impaired hand function is associated with the severity of OA, pain, joint involvement and the presence of nodes (Bagis et al, 2003). Furthermore, symptomatic OA may be associated with depression and disturbed sleep, which are additional contributors to disability (Allen et al, 2008; Parmelee et al, 2015).

Thus, OA, wherever it occurs, typically causes pain, alters function and leads to a significant deterioration in the quality of life (CDC, 2001).

The art of history taking in diagnosing and assessing the severity of OA is focused on differentiating OA joint pain and loss of function from other joint diseases, in particular the chronic inflammatory arthritides as well as acute joint diseases such as gout, septic arthritis and flares of crystal-induced arthritis.

5.2 Physical examination

A physical examination should be performed to confirm and characterise joint involvement and to exclude pain and functional syndromes arising from other causes, especially peri-articular structures, neurological disorder and inflammatory arthritis. Note however, that a normal examination does not rule out the diagnosis of OA, especially early or mild OA.

- **Joint swelling:** joint enlargement results from joint effusion and/or osteophytes and/or synovitis. Bony swelling is easily recognised in superficial joints such as the finger joints or knees. A synovial effusion may be seen during OA flares, but can also occur during chronic phases as a persistent feature. It is most easily detected in knees by the evidence of patellar shock (tap) or by elicitation of a fluid thrill (wave test). In the digital joint, only synovitis can be detected since it is a small joint with a limited cavity.
- **Joint tenderness:** joints are usually tender during active motion testing and under pressure. Limited passive movement can be the first and only physical sign of symptomatic OA. Bursitis, tendinitis, muscle spasm and,

especially for the knee, a torn meniscus, can cause the same pain syndrome and must be carefully sought during examination. Crepitus, an audible or palpable sensation of crunching or crackling, is commonly felt on passive or active mobilisation of an OA joint and may result from cartilage loss, joint surface irregularity or intra-articular debris. Although crepitus can be present with passive motion, it is most commonly demonstrated by active motion of the joint.

- Joint deformities and subluxation reflect advanced disease resulting from cartilage loss, collapse of subchondral bone, formation of bone cysts and bony overgrowth. This destruction contributes to misalignment, joint instability and limb (usually manifest as leg) shortening.
- Gait: examination of the legs with the patient standing and walking (i.e., to facilitate detection of varus or valgus malalignment) is necessary to investigate the presence of malalignment and abnormal gait (see sections 8.2 and 8.4). The appropriate use of a cane may be assessed during walk examination. Altered gait patterns can also be caused by a conscious or subconscious attempt to protect the joint or minimise pain.
- Soft tissues and bursa areas should be examined in parallel, as they can be amenable to local treatment, such as glucocorticoid injections.

Caution should be exercised in attributing pain to the correct region, for example patients with hip OA may report pain in the knee region due to referred pain or biomechanical dysfunction. In these cases, moving the knee causes no pain, whereas hip movement is painful, and the range of hip motion is limited. Patients with hip OA also have symptoms mimicking a crural pain. Careful neurological and spine examination usually rules out this diagnosis.

6 Imaging OA

The diagnosis of OA is often obvious after an interview and physical examination, in particular when other diagnoses can be excluded. In straightforward presentations, radiological investigation is often not necessary to confirm the diagnosis of hand, knee or forefoot OA. However, some regions and clinical scenarios require a radiological examination to support the history and clinical assessment and to facilitate the exclusion of other diseases including avascular osteonecrosis, Paget's disease, algodystrophy, inflammatory arthropathies and stress fractures. Less commonly involved locations such as the ankle, shoulder or elbow, also require radiological examination. Radiographic assessment is helpful to diagnose OA, and also useful to establish the severity of joint damage, to monitor disease activity progression and any response to therapy, and to look for complications of the disorder or the treatment (Cibere, 2006).

EULAR has developed guidelines for the use of imaging in the management of peripheral joint OA (Sakellariou et al, 2017*) (Table 4). Seven pragmatic recommendations based on scientific evidence and expert opinion were provided, focusing on clinical practice rather than research.

Table 4 Use of imaging in peripheral joint OA: recommendations, levels of evidence and level of agreement (LoA) – order according to topic (making a diagnosis, monitoring disease, role in prognosis, treatment) (Reproduced from Sakellariou et al, Ann Rheum Dis 2017. doi: 10.1136/annrheumdis-2016-210815.)

No.	Proposition	LoE	LoA, mean (95% CI)
1	Imaging is not required to make the diagnosis in patients with typical presentation of OA (usage-related pain, short duration morning stiffness, age > 40, symptoms affecting one or a few joints)	III-IV	8.7 (7.9 to 9.4)
2	In atypical presentations, imaging is recommended to help confirm the diagnosis of OA and/or make alternative or additional diagnoses.	IV	9.6 (9.1 to 10)
3	Routine imaging in OA follow-up is not recommended. However, imaging is recommended if there is unexpected rapid progression of symptoms or change in clinical characteristics to determine if this relates to OA severity or an additional diagnosis.	III-IV	8.8 (7.9 to 9.7)
4	If imaging is needed, conventional (plain) radiography should be used before other modalities. To make additional diagnoses, soft tissues are best imaged by US or MRI and bone by CT or MRI.	III-IV	8.7 (7.9 to 9.6)
5	Consideration of radiographic views is important for optimising detection of OA features; in particular for the knee, weightbearing and patellofemoral views are recommended.	III	9.4 (8.7 to 9.9)
6	According to current evidence, imaging features do not predict non-surgical treatment response and imaging cannot be recommended for this purpose.	II-III	8.7 (7.5 to 9.7)
7	The accuracy of intra-articular injection depends on the joint and on the skills of the practitioner and imaging may improve accuracy. Imaging is particularly recommended for joints that are difficult to access due to factors including site (eg, hip), degree of deformity and obesity.	III-IV	9.4 (8.9 to 9.9)

LoE, level of evidence (Ia, meta-analysis of randomised controlled trials; Ib, at least one randomised controlled trial; IIa, at least one controlled study without randomisation; IIb, at least one other type of quasi-experimental study; III, non-experimental descriptive studies, such as comparative studies, correlation studies and case-control studies; IV, expert committee reports or opinions or clinical experience of respected authorities, or both); LoA: 0-10 numerical rating scale. OA, osteoarthritis; US, ultrasonography.

6.1 X-ray imaging

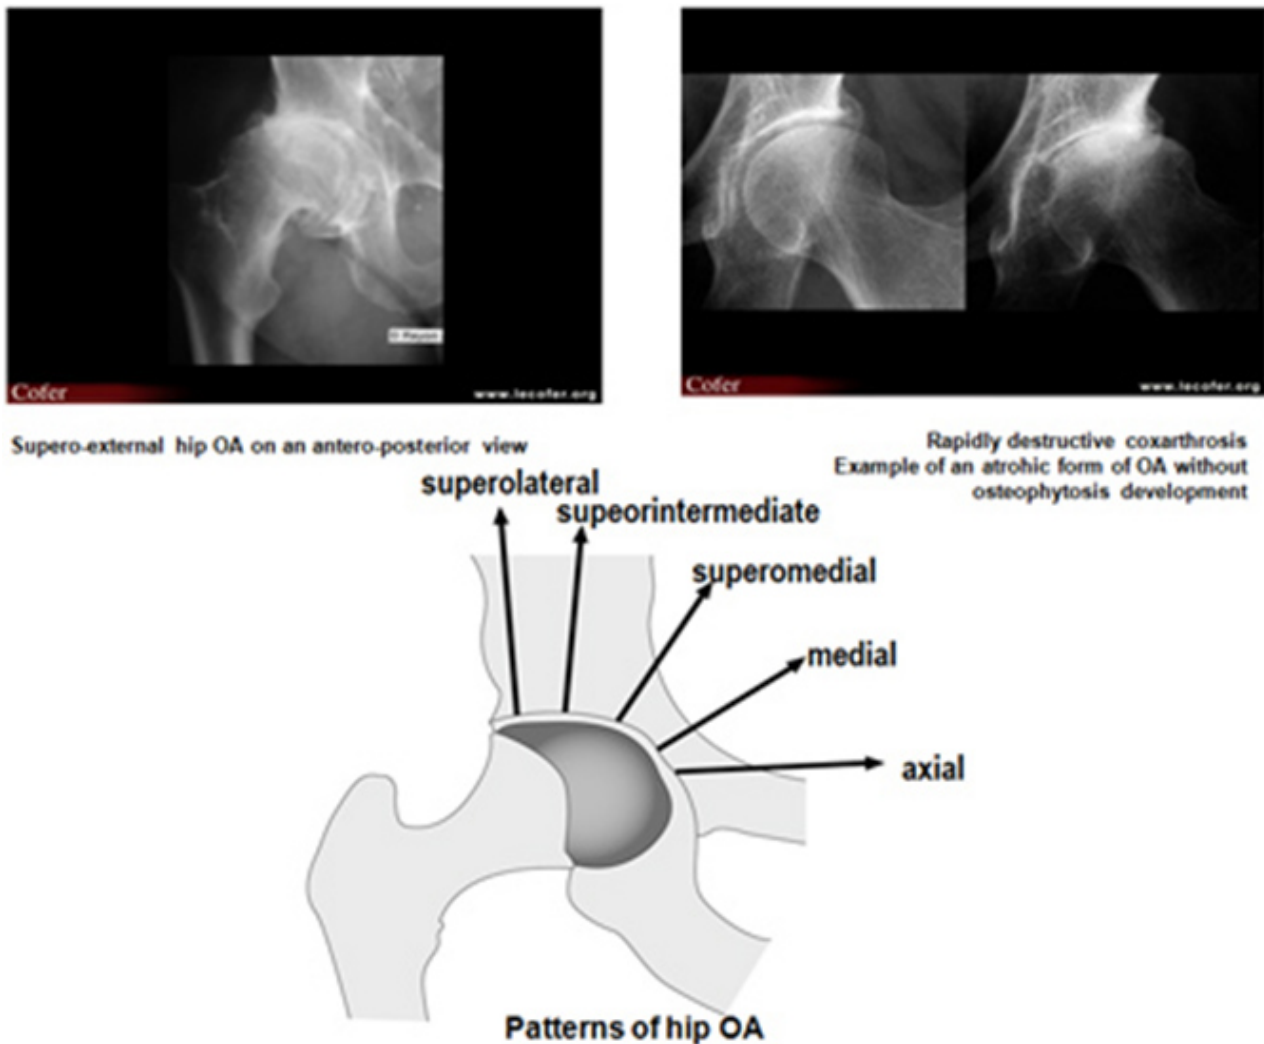

Weight-bearing X-rays are mandatory for knee and hip OA. However, standard radiographs cannot always diagnose early OA. The radiographic hallmarks of the most common form of OA, also called 'hypertrophic OA', include localised joint space narrowing, subchondral bone sclerosis, osteophyte formation and bone cysts. Subchondral bone sclerosis and joint space narrowing are classically seen in more advanced OA. However, clinical symptoms and radiographic findings are poorly correlated, many joints with radiographic evidence of OA remain asymptomatic and, conversely, the joints of many patients with severe symptoms can appear only marginally affected on X-ray (Dieppe et al, 1997; Hannan et al, 2000; Bedson and Croft, 2008). Adequate

radiographic views should be considered for detection of OA features. For the knee, flexed views demonstrated superiority compared to fully extended views in detecting joint space narrowing, and greater sensitivity to change and reproducibility. In addition, patellofemoral compartment is better assessed with skyline views than with lateral projections (Sakellariou et al, 2017*).

Demineralisation is not a classical feature of OA and its presence strongly suggests an inflammatory arthropathy or algodystrophy. Joint space narrowing is related to a decreased volume of articular cartilage, and also to meniscal cartilage lesions and cartilage extrusion (Raynauld, 2003). Although standard X-rays are useful for monitoring the evolution of OA, the optimal frequency of radiographs that can best inform practice is not well defined. Gross deformity, subluxation and loose bodies may occur in advanced cases. 'Atrophic' OA is a rare form of OA, characterised by an absence of osteophytes and sclerosis; it usually involves the hip and especially rapidly destructive hip (figure 9) (Ledingham et al, 1992; Rosenberg et al, 1992) and may chiefly occur in women (Conrozier et al, 2004). Ankylosis in OA is not a feature, with the exception of erosive hand OA (Punzi et al, 2004).

Other investigations are rarely necessary to confirm the diagnosis of OA, but they are sometimes useful to exclude alternate possibilities in a difficult differential diagnosis. In addition, recent developments in imaging are providing novel insights into the pathophysiology and course of the disease (Roemer et al, 2014). MRI and ultrasound are more suitable for the assessment of soft tissues, while bone is better explored with CT. Although such imaging techniques, in particular MRI, are receiving a lot of attention in the literature, there is a gap between their use in study settings and their usefulness in daily clinical practice.

Figure 9 Hip osteoarthritis. (A) Antero-posterior view of supero-external hip osteoarthritis (OA). (B) Rapidly destructive coxarthrosis; example of an atrophic form of OA without osteophytosis development. (C) Patterns of hip OA. (Source: Cofer, <http://www.lecofer.org/>)

6.2 MRI imaging

All the tissues involved in OA, including cartilage lesions, fluid effusion, subchondral bone marrow oedema, low-grade synovitis, and meniscus or ligament lesions, can be seen by MRI (Peterfy, 2000). MRI can be useful for excluding tumour or avascular osteonecrosis. Changes in cartilage thickness can be detected early by MRI (Calvo et al, 2001). The pain and progression of knee OA seem to be associated with synovitis and bone marrow oedema seen on MRI, but this remains controversial (Felson et al, 2003; Conaghan, 2006; Conaghan et al, 2006; Yusuf et al, 2011). Bone marrow oedema is an MRI observation, but comparisons with histological specimens from knee replacement have shown that necrosis, fibrosis and abnormal remodelled trabecula are the most common features (Conaghan et al, 2006), therefore bone marrow lesion is a more appropriate name. The presence of bone resorption is also clearly recognised as part of OA progression (Felson et al, 2001; Felson et al, 2003). The meniscus tears seen by MRI are common in middle-aged and older adults, with or without knee pain. Thus, although MRI accurately detects meniscus or ligament damage, which are known to be

associated with increased OA progression, this finding is not unusual at the age of osteoarthritic patients and thus does not influence therapeutic management and should not by default lead to aggressive procedures (Pessis et al, 2003; Englund et al, 2012). MRI is now being used to assess the quantity and function of cartilage, synovium and bone. For instance, quantitative MRI provides non-invasive measures of cartilage degeneration at the earliest stages of joint degeneration and will likely be an important tool in early OA studies (Sharma et al, 2014). In hand OA, MRI gives more information than X-ray alone, and might be reliable to assess both structural and inflammatory changes (Kortekaas MC et al, 2015). MRI lesions (bone marrow lesions, synovitis and joint space narrowing) may also predict radiographic progression of hand OA (Haugen et al, 2016; Damman et al, 2017). However, as stated above, the routine use of MRI has no clinical application in daily practice (Sakellariou et al, 2017*). In addition, meta-analyses suggest that MRI can detect OA with an overall high specificity and moderate sensitivity when compared with various reference standards, thus lending more utility to ruling out OA than ruling it in. The sensitivity of MRI appeared to be below the current clinical diagnostic standards (Menashe et al, 2012).

6.3 Ultrasound

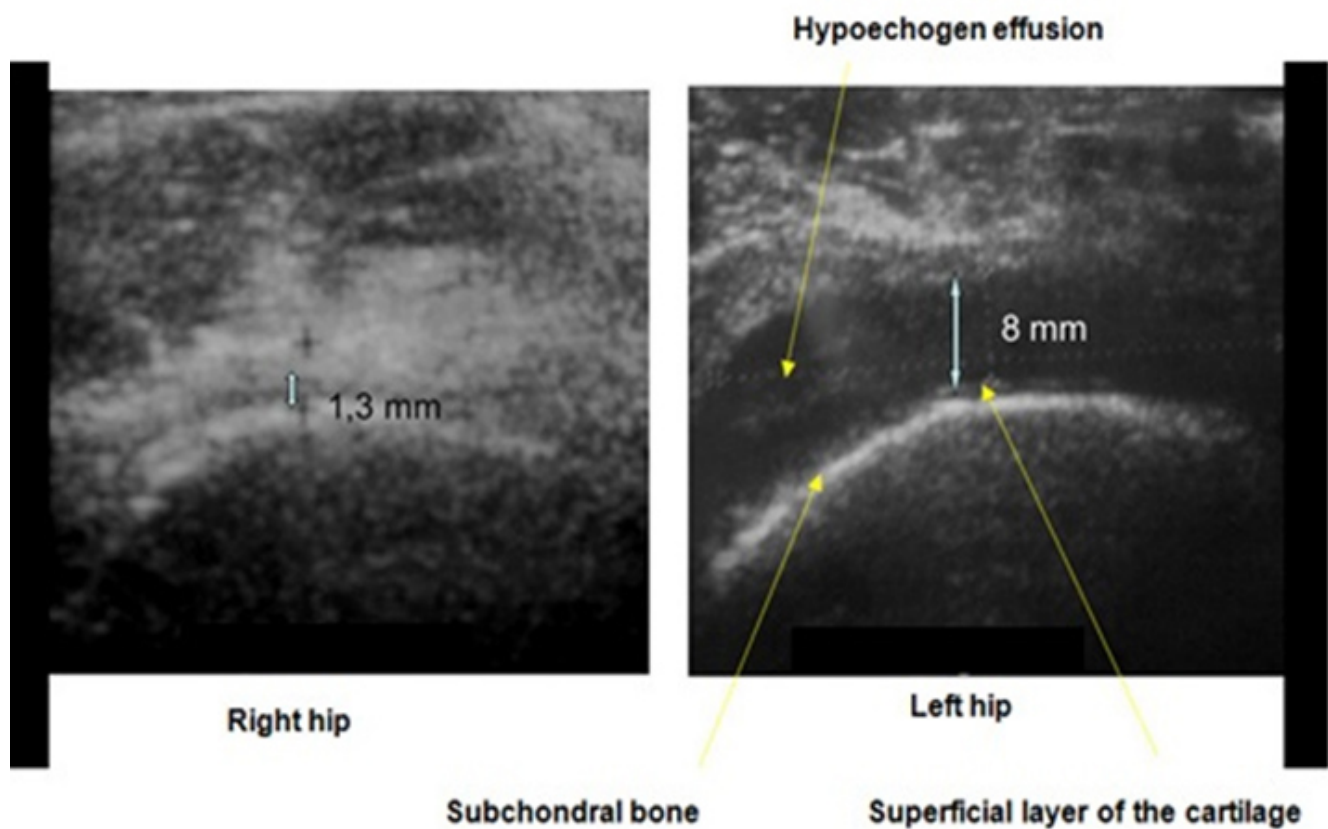

Ultrasound is currently only useful for detecting joint effusions, including a minimal effusion undetectable upon clinical examination, changes in cartilage such as fibrillation of cartilage or cleft formation, synovitis and osteophytes (Iagnocco, 2014) (figure 10). Popliteal cysts can also be visualised by ultrasound, and potential complications including compression of adjacent vascular structures can be diagnosed. Many studies are currently evaluating the advantages of this procedure in terms of early diagnosis, evaluation of pain symptoms, severity and prognosis. Ultrasonography has been extensively studied in knee OA to detect inflammatory flares and popliteal cysts and could serve to assess treatment efficacy (Acebes et al, 2006). Ultrasonography may also be useful in hand OA, to differentiate between erosive and non-erosive OA. Ultrasound-detected inflammatory features may also predict the development of erosions in hand OA (Kortekaas et al, 2016). Ultrasonography can be used to perform aspirations and injections within the joint and peri-articular tissue. However, ultrasound imaging is limited by its inability to visualise the entire cartilage surface, by artefacts caused by the position of the probe, and finally by inter- and intra-observer variations. Thus, this imaging procedure needs standardisation before it can be used in daily clinical practice, except for specific situations (i.e., popliteal cysts, guided aspiration or injection) (Sakellariou et al, 2017*).

6.4 Arthroscopy

Arthroscopy visualises cartilage, synovial membranes, osteophytes and meniscal lesions. Note that this approach, like MRI, may detect findings of dubious significance such as meniscal lesions, which are frequent in patients over 60 but rarely the cause of pain. On the other hand, dissection of the meniscus could be highly deleterious by accelerating the progression of OA. This procedure is employed less since the use of MRI

became more common. Definite conclusions about the global clinical utility of MRI when compared with arthroscopy have not yet been made (Quatman et al, 2011).

Figure 10 Hip osteoarthritis: ultrasonography.

7 Laboratory tests

Blood tests are not routinely indicated to confirm the diagnosis of uncomplicated chronic pain arising from clearly defined OA. The erythrocyte sedimentation rate and C-reactive protein concentration are usually within the normal range for age. Highly sensitive C-reactive protein seems elevated in some patients with erosive hand OA, but its use is not recommended for daily clinical practice (Punzi et al, 2004). Low titres of rheumatoid factors can be found, reflecting the median age of patients with OA and not differing in that respect from control populations. Laboratory tests may be performed to rule out a metabolic arthropathy (such as gout or haemochromatosis) or inflammatory arthritis, or to investigate the adverse effects of drugs.

Synovial fluid in primary OA is non-inflammatory and should only be examined if another arthropathy or septic arthritis is suspected. Assessment of crystals is thus necessary. Analysis of synovial fluid typically reveals a white blood cell count of less than 2000 per mm³, sterile, without any crystals (Dougados et al, 1996*). However, apatite crystals may appear in synovial fluid with progression of the disease in patients with OA, and their presence is common in the most severe forms of OA (Nalbant et al, 2003).

Histological examination, performed during surgical joint replacement, reveals non-specific changes of chronic mild inflammation or some degree of fibrosis (see section 2, Pathology). For OA, synovial biopsies currently do not contribute to the diagnostic process.

Biochemical markers of cartilage or bone turnover or remodelling are not currently assayed in the day-to-day management of OA because no single marker is yet adequate for predicting or monitoring OA in an individual patient. Biomarkers in cohort studies and in clinical trials are useful to elucidate the physiopathology of disease and to support a clinical impression of the disease state of OA. Candidate biochemical markers of joint tissues in OA can reflect different actors of OA (bone, cartilage, synovitis, systemic inflammation) and the different states of these tissues (i.e., degradation or synthesis).

The objective in the future will be to use biomarkers in OA diagnosis, before damage can be observed on radiographs. The main limitation in using tissue-derived biomarkers including collagen breakdown products is the need to adjust for different clinical features such as sex, age, body mass index and hormonal status (including hormone replacement therapy). Biomarkers may have some other sources of variations such as diurnal variation or influence of exercise, and reflect not just one target joint but all joints in an individual. Biomarkers are also used in the prediction of progression. In some studies, joint space narrowing progression seems positively correlated with markers of degradation of type I and II collagen (i.e., C- and N-telopeptide) and cartilage oligomeric matrix protein (COMP) corresponding to degradation of non-aggreacan and non-collagen proteins (Charni-Ben and Garner, 2007). Because of the complex involvement of bone cartilage synovium and systemic inflammation, only a combination of several biochemical markers will adequately predict disease progression (Davis et al, 2007). These new biomarkers will serve probably also to predict and/or monitor the efficacy of new disease-modifying OA treatment (Martel-Pelletier et al, 2017). Whether it will be possible to utilise biomarkers meaningfully to characterise the disease state in an individual patient remains to be seen (Kraus, 2006*; van Spil et al, 2010). As stated above, there is no evidence that one of the biomarkers currently under study should be used to diagnose, monitor or predict disease course.

8 Clinical subsets of OA

8.1 Several forms of OA

OA tends to affect distal interphalangeal joints, the trapezio-metacarpal joint, the knee, hip and intervertebral facet joints. Commonly, more than one joint is involved and there is a significant association between contralateral joints that is stronger than the association between different joint groups. Knee and hip OA are both associated with hand OA, the association between knee and hand OA being stronger (Crushnagan and Dieppe, 1991; Croft et al, 1992b; Hochberg et al, 1995; Cooper et al, 1996; Hirsch et al, 1996). Wrists, elbows, metacarpophalangeal joints and shoulders are usually less likely to be affected by OA. If they are, this may suggest the presence of secondary OA or another diagnosis.

Some authors individualise several forms of OA:

- Primary OA, corresponding to the classical definition and description of the disorder, differs from the secondary form which has an identifiable aetiology such as a congenital, inflammatory or metabolic disease able to explain the degenerative process occurring in the joint. Thus, if there is concomitant disease, the target joint is generally considered to be affected by secondary OA. Secondary OA shares some features with primary OA but, in addition, is characterised by the presence of signs and symptoms suggesting an underlying cause. The identification of the primary disease is valuable since specific therapies can be used.
- Sometimes, physical symptoms can suggest such a diagnosis: for example, metacarpophalangeal involvement during hand OA suggests the presence of an inflammatory or metabolic disorder. Secondary causes of OA are reported in box 1. Some of them are more of a risk factor (i.e., meniscectomy or occupational arthropathy) and the distinction between aetiological and predisposing factors is not always easy. Of note, several predisposing factors may be present in case of primary OA.
- As mentioned above, the most common form of OA, also called ‘hypertrophic OA’, including classical features of OA (i.e., localised joint space narrowing, subchondral bone sclerosis, osteophyte formation and bone cysts) has to be differentiated from the rare ‘atrophic’ form in which an absence of osteophytes and sclerosis is observed. This last form is often associated with rapid progression and is thus called ‘rapidly destructive arthropathy’ (figure 9).
- Primary generalised nodal OA corresponds to a more severe disease differentiated only by polyarticular involvement and the presence of multiple Heberden’s and Bouchard’s nodes. This subtype of OA should lead to investigation for a metabolic arthropathy such as chondrocalcinosis.
- Erosive inflammatory OA involving the hand, which has a greater clinical burden than non-erosive hand OA in the general population (Kwok et al, 2013). However, whether erosive hand OA is a specific entity or simply a severe form of the disease remains debated (Marshall et al, 2015).

8.2 Knee

OA can involve the medial tibiofemoral, the lateral tibiofemoral and the patellofemoral compartments. First, a misalignment of the lower limb might be noted if present. It is a cause of compartmental knee OA (e.g., varus angulation of the knee responsible for medial tibiofemoral damage and valgus angulation for lateral tibiofemoral damage). The lateral tibiofemoral compartment is involved mainly in women with a genu-valgum misalignment. Varus and valgus angulations can affect the range of motion and accelerate joint space narrowing. They may thus enhance the development of OA. The precise location of pain can indicate which compartment of the joint is involved. Patients also sometimes report knee instability—the knee ‘gives way’.

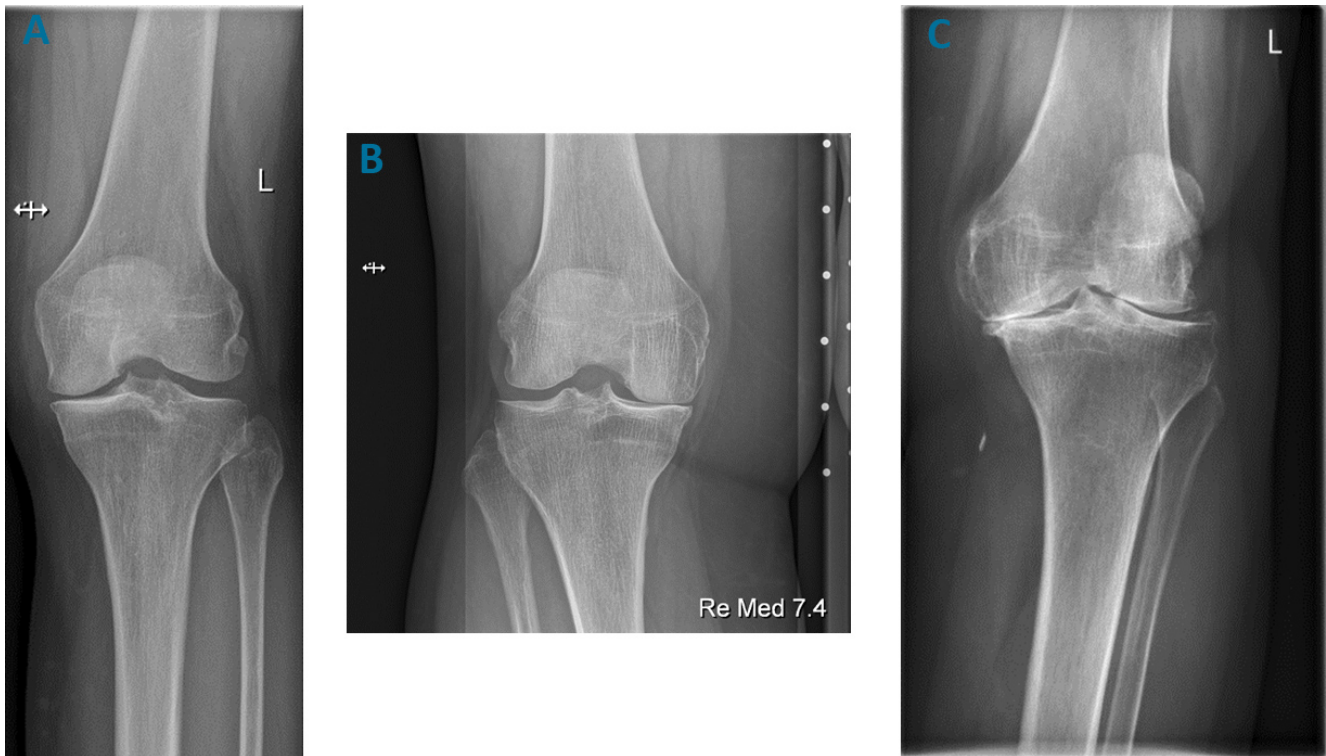

This is likely linked to decreased muscle strength rather than true meniscus damage. Posterior pain can be due to an abundant effusion.

The knee can lock if loose bodies or fragments of cartilage get into the joint space. This is relatively rare, but care should be taken to distinguish between the stiffness experienced after prolonged immobilisation of a limb and true mechanical locking, which suggests a meniscus lesion. Physical examination for knee OA should begin by investigating the gait, using a slow walk to check for an extension defect. The presence of bone swelling should be noted. Physical examination may find synovitis or fluid effusion. Crepitus is detected upon passive motion of the patella or knee flexion/extension testing. The range of motion may be normal or limited by structural alterations or abundant effusion. A popliteal (Baker's) cyst communicating with the joint space is common. The cyst may rupture into the posterior calf muscles, mimicking venous thrombosis, and should be considered in 'Doppler negative' leg swelling in the acute setting. Local tenderness along the joint line is characteristic of tibiofemoral OA. Peri-articular structure examination may reveal anserine bursitis, infrapatellar or prepatellar bursitis, and instability of the collateral ligament. Trochanteric bursitis can also cause pain radiating through the tensor of fascia lata and ilial-tibial band to the lateral part of the knee. An acute tear of the anterior cruciate ligament may cause pain, but is unusual in middle-aged subjects. The presence of anterior laxity should also be evaluated, since a decrease in anterior-posterior laxity is associated with decreased joint space. A lax joint is defined by the excess displacement or rotation of the tibia with respect to the femur in the varus-valgus direction. Joint laxity increases functional disability due to weak muscles. A positive Lachman's test may be elicited. Of note, cartilage erosion is frequently associated with meniscal degeneration which is not considered the source of pain and does not require specific therapeutic management (Ike and Arnold, 1992). The circumference of the quadriceps muscle should be noted to detect any atrophy. A weak quadriceps femoris is a known disability factor in knee OA. This weakness can more convincingly explain the knee 'giving way' than the often-suggested ligament instability. Finally, the hip should be examined routinely since it may refer pain to the knee.

The syndrome of patellofemoral OA is very specific: pain occurs mainly during climbing or descending stairs, while pain during walking on level ground is usually a symptom originating in the tibiofemoral compartment. Involvement of the patellofemoral compartment can cause anterior and/or posterior pain. Patellofemoral pain is produced by the patella pressing on the femoral condyles, or after patella subluxation or blocking elevation of the patella during quadriceps contraction when the knee is extended. Patellofemoral OA is usually better tolerated than tibiofemoral OA, but severe disability is also possible.

X-rays for knee OA should include bilateral comparative images of both knees: a weight-bearing, semi flexed posterior-anterior (PA) view and a lateral and skyline view (Sakellariou et al, 2017*). Classical features are focal joint space narrowing, osteophytes, subchondral bone sclerosis and subchondral 'cysts' (Zhang et al, 2010*) (figure 11).

Figure 11 Osteoarthritis of the knee. (A) Slightly narrowed medial femoro tibial joint space of the left knee with osteophytes (Kellgren–Lawrence grade II). (B) Moderately narrowed medial femoro tibial joint space of the right knee with multiple osteophytes (Kellgren–Lawrence grade III). (C) Marked joint space narrowing (tricompartimental) of the left knee with large osteophytes (Kellgren–Lawrence grade IV).

The patellofemoral compartment is investigated using an axial (skyline) view with variable degrees of knee flexion or a lateral view. Skyline view have a greater reliability and sensitivity to change than lateral view (Sakellariou et al, 2017*). However, when both the skyline and lateral views are used with the PA, 98.7% cases of radiographic OA can be identified (Duncan et al, 2006). The tibiofemoral compartment is evaluated by a semi-flexed posterior-anterior view (Zhang et al, 2010*).

Squaring of the femoral condyle, intercondylar spurring and varus or valgus misalignment of the affected limb can occur. Radiographs of the hip, the knee and the ankle made on one long film with the patient standing upright may identify angular deformity. The patient must be able to place his/her full weight on the affected limb for a true measurement of limb deformity. A mechanical axis of 0° to 3° of varus is considered to be within normal limits (Iorio and Healey, 2003).

8.3 Hand

The hand is one of the most common sites of OA. Post-menopausal women are more frequently affected than men (sex ratio 10:1) and genetic factors explain familial aggregation (Spector et al, 1996). Hand OA begins mostly after 40 years of age (Zhang et al, 2009*) and usually affects multiple hand joints at the same time, especially the distal interphalangeal, proximal interphalangeal and first carpometacarpal joints of the hand

(Kloppenburg and Kwok, 2011). A preferential pattern of distribution is found, consisting of involvement by row, by ray and symmetrical. The metacarpophalangeal joints are less commonly involved, but if implicated, an inflammatory or metabolic arthropathy, such as rheumatoid arthritis or haemochromatosis, should be investigated.

The four main complaints of hand OA are: pain on usage, mild morning stiffness, disfigurement and disability, with impaired manual dexterity and reduced hand mobility leading to restriction of occupational activity. Bony enlargements of the proximal interphalangeal joints are called Bouchard's nodes, whereas those of the distal interphalangeal joints are called Heberden's nodes (figure 12). These nodes are responsible for malalignment of the fingers. They can develop gradually with acute inflammatory phases characterised by severe pain and synovitis mimicking an inflammatory arthropathy, such as psoriatic arthritis. A differential diagnosis can be very difficult in such cases, in particular since psoriasis is a common disease. A diagnosis of psoriatic arthritis should be suspected more strongly when the patient shows signs of psoriatic nail disease or in the presence of other affected joints. In hand OA, the swollen joints may feel either soft and fluctuant (corresponding to small synovitis) or hard (because of the presence of osteophytes). Nodes can be associated with mucinous cysts which can disappear spontaneously or persist indefinitely or sometimes communicate with distal interphalangeal joint space. As the disease progresses, there is characteristic loss of mobility and flexion and deviation of the distal phalanx. The disease course is usually insidious, but sometimes acute.

OA frequently involves the first carpometacarpal joints, causing painful motion, tenderness, and squared deformation of the radial base of the thumb, and fixed adduction that in turn leads to severe disability (Bijsterbosch et al, 2010) (figure 12). This location is clearly associated with hypermobility as a risk factor (Jonsson et al, 1996). De Quervain's tenosynovitis can be associated throughout the disease process and exacerbates this functional limitation.

Polyarticular hand OA often co-occurs with knee and hip OA, and with OA at other joint sites (generalised OA). Therefore, patients with hand OA should also be examined for OA at other joint sites.

Posterior-anterior X-rays of both hands, including the wrists, can reveal characteristic features of OA (figure 13), but radiography is not necessary for diagnosing hand OA. Erosions of the interphalangeal distal joints on X-rays (seagull erosions) are prominent features in a subset of OA patients called "erosive OA". This is more common in post-menopausal women and characterised by inflammatory pain and synovitis and leads to joint deformity and occasionally ankylosis. The fingers are often significantly deformed within a short number of years, with firm bony swelling and consequent reduced joint motion. At advanced stages, flares and pain tend to subside. A slight increase in erythrocyte sedimentation rate or C-reactive protein may be present. The differential diagnoses are psoriatic arthritis, less likely rheumatoid arthritis and, very rarely, multicentric reticulo-histiocytosis.

Figure 12 Hand osteoarthritis: clinical aspects. (A) Typical features of hand osteoarthritis (OA) with Heberden's and Bouchard's nodes. Note the misalignment related to the distal (Heberden's) nodes. (B) Typical feature of trapezo-metacarpal OA with deformation of the base of the thumb. (Source: Cofer, <http://www.lecofer.org/>)

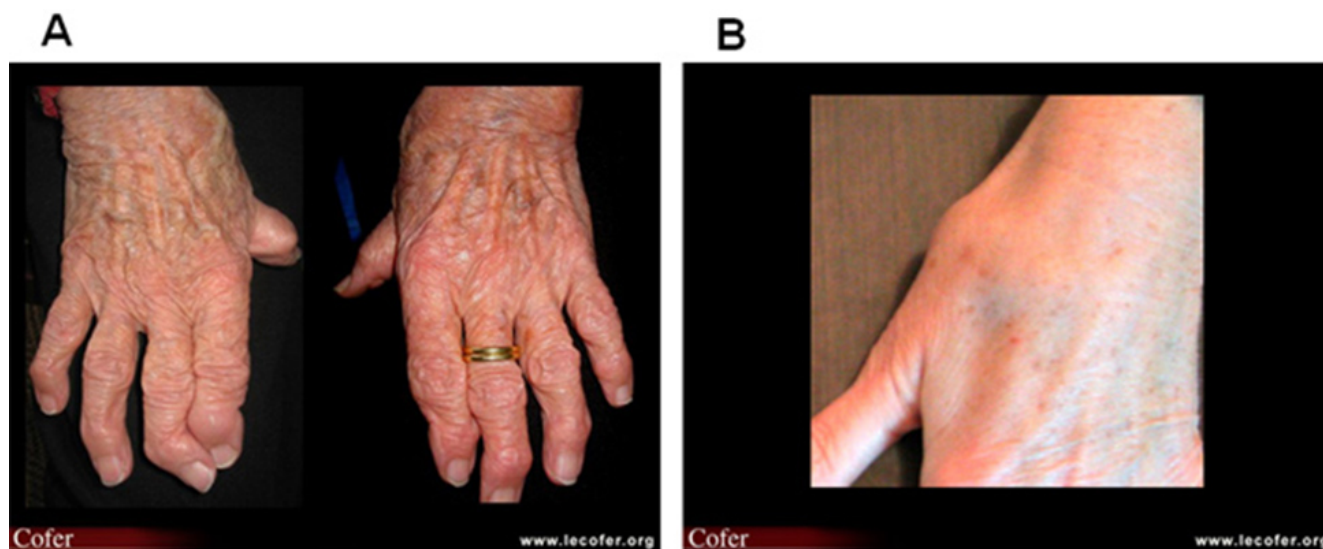

Figure 13 Osteoarthritis of the hand. Diffuse osteoarthritic impairment of bilateral PIP and DIP joints with signs of destruction, bilateral osteoarthritis of MCP V and bilateral thumb osteoarthritis (CMC I and STT joint). CMC, carpometacarpal; DIP, distal interphalangeal; MCP, metacarpophalangeal; PIP, proximal interphalangeal; STT, scaphotrapezotrapezoidal.

8.4 Hip

Hip OA develops equally in men and in women (Srikanth et al, 2005) and may be unilateral or bilateral.

Unilateral hip OA increases the likelihood of involvement of the contralateral joint (Cooper et al, 1996). Beside

age and genetics, common risk factors include incongruency (such as dysplasias), joint laxity, increasing BMI, high levels of certain exercise and heavy manual labour (Aresti et al, 2016).

Hip pain is classically present during weight-bearing and associated with antalgic gait. Pain can be located in the buttocks and the groin region, and may radiate down to the anterior thigh. Occasionally, patients present with predominantly knee pain (referred pain) and its true origin (hip OA) is overlooked.

Patients often report significant disability during activities of daily life, for example they find it difficult to reach their feet to cut their toenails or to tie their shoelaces. Flares are frequent, with pain at night and morning stiffness, sometimes associated with the presence of an effusion. In this case, further investigations, such as ultrasonography or MRI, should be considered in order to identify an inflammatory flare with synovitis or effusion. Advanced OA is often preceded by a progressive phase with increasing aggravation of symptoms (between 3 months and 3 years). The symptoms seldom improve, except in concentric hip OA with marked osteophytosis. Examination reveals a limited range of movement, although this is not always present. The leg is often held in external rotation with the hip flexed and adducted. In early disease, limited movement may only be seen when extension is tested. Groin pain can be reproduced by palpation during physical examination. This pain can also be reproduced by passive movement of the hip, especially upon internal rotation and flexion. Quadriceps muscle weakness is also a common finding. The main differential diagnoses are cruralgia (in which neurological signs are usually present), psoas and iliopsoas lesions, and trochanteric bursitis (characterised by pain at the external surface of the hip and thigh but normal hip motion). Consideration should also be given to intra-pelvic lesions if clinical examination is entirely normal in the face of a convincing history. In case of difficult diagnosis, injection with local glucocorticoids and lidocaine in the joint or in the trochanteric bursitis can be helpful.

Radiological examination should be bilateral and comparative, and include an anteroposterior pelvis view in the weight-bearing position with internal rotation of the feet (15° to 20°), an anteroposterior view centred on one hip, and a false profile incidence corresponding to an oblique view which seems especially of interest in case of superolateral space narrowing OA (Lequesne, 2002). All these radiological images are useful to assess with precision joint space narrowing of the hip (figure 14). The superior-external pole is most often involved (superior-lateral, superior-intermediate and superior-medial) (figure 9). Medial OA is much rarer, occurs mainly in women and progresses slowly. Hip OA may be rapidly destructive, defined by Lequesne as joint space narrowing at more than 2 mm/year, that is, a loss of more than 50% of the joint space within 1 year (Lequesne and Ray, 1989). Bone sclerosis and osteophytes are rare in such patients. Importantly, hip pain and radiographic hip OA are two substantially discordant outcomes: a minority of patients with hip pain has radiographic hip OA, and only a minority of patients with radiographic hip OA has hip pain (Kim et al, 2015). A hip joint replacement is usually considered within a few months of the first symptoms being recognised. The

common aetiologies of secondary hip OA include congenital dysplasia, avascular osteonecrosis and previous trauma.

Figure 14 Osteoarthritis of the hip. (A) Bilateral joint space narrowing and presence of osteophytes. (B) More detailed view of the left hip; clear signs of joint space narrowing, osteophytes and sclerosis.

8.5 Spine

Spine and peripheral OA share anatomical similarities and common pathophysiological processes. The posterior facet articulations are true diarthrodial joints and as such are susceptible to OA. The other structures involved in spine OA are intervertebral fibrocartilaginous discs and vertebral bodies which are damaged. Some authors make the distinction between degenerative changes involving the discs and vertebral bodies and those involving apophyseal joints, the latter being generally considered similar to peripheral joint OA.

Common regions of involvement include the cervical and lumbar spine, whereas the dorsal spine is only exceptionally involved because of the stability provided by the thoracic cage. Osteophytes of the vertebrae can narrow the foramina and compress nerve roots producing, in addition to back pain, a radicular pain with specific topography, especially when it is associated with disc herniation, ligamentous hypertrophy, spondylolisthesis or foraminal narrowing from apophyseal joint subluxation. Weakness and numbness of the arms or legs have also to be assessed. Spinal cord lesions as a result of OA of cervical and dorsal spine are possible but classically not in the case of lumbosacral spine involvement because the spinal cord ends at the level of L1; however, cauda equina syndrome with sphincter dysfunction may develop.

The pain has some typical features such as intermittent radicular claudication, exacerbation during extension of the spine and relief during flexion. The patient may stand with the lumbar spine flexed to reduce pain.

In some individuals, osteophytes may extend along the entire length of the spine, with prominent involvement of the thoracic region and osteophyte fusions. This hyperostosis is also called Forestier's disease and can include extraspinal sites. The usual term used for this condition is diffuse idiopathic skeletal hyperostosis (figure 15).

Figure 15 Diffuse idiopathic skeletal hyperostosis (also called Forestier's disease). Dorso-lumbar radiographs showing extensive osteophytosis. (Source: Cofer, <http://www.lecofer.org/>)

Radiological evidence of degenerative disease in the spine may be extensive but sometimes without major pain. However, minor spur formation located in a critical area can be symptomatic.

8.6 Foot and ankle

OA commonly attacks the first metatarsophalangeal joint. OA at the other metatarsophalangeal joints occurs to a lesser degree. Patients have difficulty walking and the overlying skin can appear inflamed, especially if tight shoes are worn. A bursitis can also appear. A valgus deformity is very frequent (hallux valgus) and there may be ankylosis of the joint (hallux rigidus). There are usually radiological features of foot and ankle OA, even in subjects aged less than 40 years. The tarsal joints may be involved in cases of pes planus. Tibial-talar and subtalar OA are generally due to trauma, misalignment or neuropathic arthropathy (figure 16). Importantly, in the absence of trauma history, ankle arthropathy should prompt diagnostic tests for hereditary haemochromatosis (Husar-Memmer et al, 2014; Richardson et al, 2017).

Figure 16 Foot/ankle osteoarthritis. (A) Osteoarthritis (OA) of the first metatarsophalangeal joint. (B) Post-traumatic ankle OA (right) with tibiotarsal joint space narrowing and subchondral bone sclerosis.

8.7 Shoulder

OA is less common in the shoulder than in weight-bearing joints (figure 17). Pain is poorly localised and occurs on movement, but pain at night during motion is also common. Examination reveals limitation of passive movement. Shoulder OA sometimes follows lesions of the rotator cuff, which promotes ascension of the humeral head. Milwaukee shoulder is a particular form of shoulder OA characterised by hydroxyapatite deposits and severe destruction of the joint (Halverson et al, 1984) (figure 18). The differential diagnosis includes acromio-clavicular disease, which gives elective tenderness on direct palpation of the joint with medial irradiation. The acromio-clavicular joints are often affected in subjects like construction workers subject to direct weight bearing to the shoulder area. Shoulder OA can also develop after vascular osteonecrosis, causing the humeral head to become aspherical.

Figure 17 Shoulder osteoarthritis. Strongly pronounced glenohumeral osteoarthritis of the left shoulder with an extremely voluminous caudal osteophyte at the humeral head.

figure 18 Milwaukee shoulder. (Source: Cofer, <http://www.lecofer.org/>)

9 Tools for diagnosis, classification and assessment of OA

9.1 Criteria for OA

Criteria for any disease may serve different purposes. Criteria can be used for the classification of patient groups, typically used for inclusion in clinical trials or population surveys, for the diagnosis of individual patients with a direct impact on clinical practice, and for the evaluation of disease severity and outcome. Caution is important when considering the use of criteria in daily clinical practice. Most disease criteria have been developed to aid the correctness of diagnosis in patients taking part in clinical studies rather than the effectiveness of individual patient diagnosis. However, many such criteria sets have been used or mis-used as guidelines or tools in patient diagnosis. The physician should always keep in mind that classification criteria have been developed by specific methods and in a specific setting (eg, primary care or tertiary referral clinics) with the goal of achieving optimal group discrimination and not the diagnosis of disease in an individual patient. Therefore, most classification criteria used in rheumatology should not be used to formally make or exclude a diagnosis in the individual patient.

As mentioned above, OA can be defined in different ways, based on clinical signs and symptoms, radiographs or other imaging tools, and by pathology. Radiographic definitions of OA usually include joint space narrowing or the presence of osteophytes; clinical definitions include the detection of abnormalities upon clinical examination such as limited movement or crepitus in a joint. As radiographs and clinics do not always agree,

symptomatic OA (and therefore probably clinically relevant OA) is usually defined as pain, aching or stiffness in a joint that also shows radiographic signs of OA.

The American College of Rheumatology (ACR) has defined 'Criteria for the classification and reporting of OA' of the hand, hip and knees (table 5) (Altman et al, 1986; Altman et al, 1990; Altman et al, 1991). These criteria are excellent examples of classification criteria. From this perspective and taking into account their goals (correct definition of groups in clinical research), sensitivity and specificity are considered very good to excellent. The sensitivity and specificity of the ACR hip criteria are estimated to be 91% and 89%, respectively, while the sensitivity and specificity of ACR knee criteria are estimated to be 91% and 86%. For hand OA, the sensitivity is 92% and specificity 98%. Taking into account their overall high specificity, such criteria can be useful as a tool in clinical practice in order to differentiate patients with OA from those with inflammatory disease. Their sensitivity is less impressive, illustrated by their limitation in differentiating patients with early OA from healthy controls. When these criteria are used, the prevalence of OA is underestimated compared with a definition based on radiographic criteria (McAlindon and Dieppe, 1989), and also these criteria cannot be used to rule out a diagnosis of OA in routine clinical practice, in particular in early stages of disease.

EULAR has developed recommendation sets for the clinical diagnosis of hand and knee OA, and showed that thorough clinical assessment alone can provide a confident diagnosis (Zhang et al 2009*; Zhang et al, 2010*). The recommendations for diagnosis can also be found on the EULAR website (www.eular.org). For knee OA, 10 recommendations were developed (table 6). According to the recommendations and the supporting evidence, the diagnosis of knee OA can be made based on the background risk (the population prevalence of knee OA), the patient's risk factors for OA (eg, age, gender, BMI, occupation), their symptoms and an adequate physical examination. Plain radiographs are the main test to consider, but are an adjunct rather than a central feature, for the purposes of diagnosis. The more positive results a patient presents, the more likely the diagnosis of OA. Knowledge of the background risk (eg, the local source population prevalence of knee OA) is crucial for estimating the likelihood of knee OA. The higher the risk in the source population, the more possible it is to diagnose knee OA based on clinical features. A confident diagnosis may therefore be made according to three symptoms (knee pain, short-lived morning stiffness and functional limitation) and determination of three signs on examination (crepitus, restricted movement and bony enlargement) without a requirement for imaging. This may be especially useful for primary care. Nevertheless, plain radiography and occasionally other investigations should be considered for the diagnosis of atypical cases when additional pathology is suspected.

Table 5 American College of Rheumatology radiological and clinical criteria for hand, hip and knee osteoarthritis

		Diagnosis of OA can be made if following criteria are met:
Hand	Clinical 1. Hand pain, aching or stiffness 2. Hard tissue enlargement of 2 or more of 10 selected joints* 3. Fewer than 3 swollen metacarpophalangeal joints 4a. Hard tissue enlargement of 2 or more distal interphalangeal joints 4b. Deformity of 2 or more of 10 selected hand joints*	1, 2, 3 and 4a or 1, 2, 3 and 4b (tree format)
Hip	Combined clinical and radiographical 1. Hip pain 2. Femoral and/or acetabular osteophytes on radiographs 3a. ESR \leq 20 mm/h 3b. Axial joint space narrowing on radiographs	1 and 2 or 1, 3a and 3b (tree format)
Knee	Clinical 1. Knee pain 2. Age >50 years 3. Morning stiffness for <30 min 4. Crepitus on active joint motion 5. Bony tenderness 6. Bony enlargement of the knee on examination 7. No palpable warmth Combined clinical and radiographical 1. Knee pain 2. Age >50 years 3. Morning stiffness for <30 min 4. Crepitus on active joint motion 5. Osteophytes at joint margins on radiographs	1 + at least 3 of the other clinical criteria 1 and 5 + at least 1 of the other criteria (2, 3 or 4)

*The 10 selected joints include bilateral second and third interphalangeal proximal joints, second and third proximal interphalangeal joints, and first carpometacarpal joint. ESR, erythrocyte sedimentation rate; OA, osteoarthritis.

Table 6 Diagnosis of knee OA: propositions and strength of recommendation – order according to topic (definition, subsets, symptoms, physical findings, images, laboratory tests, risk factor and differential diagnosis) (Reproduced from Zhang et al, Ann Rheum Dis 2010;69:483–9)

No.	Proposition	LoE	SOR (95% CI)
1	Knee OA is characterised clinically by usage-related pain and/or functional limitation. It is a common complex joint disorder showing focal loss, new bone formation and involvement of all joint tissue. Structural tissue changes are mirrored in classic radiographic features.	IIb	88 (83 to 92)

2	Risk factors that are strongly associated with the incidence of knee OA can help identify patients in whom knee OA is the most likely diagnosis. These include increasing age over 50 years, female gender, higher body mass index, previous knee injury of malalignment, joint laxity, occupational or recreational usage, family history and the presence of Heberden's nodes.	Ia–IIb	89 (83 to 95)
3	Subsets with different risk factors and outcomes can be defined according to: varying compartmental involvement (patellofemoral, medial tibiofemoral, lateral tibiofemoral); bone response (atrophic, hypertrophic); the global pattern of OA (generalised, localised); by crystal presence (pyrophosphate, basic calcium phosphates); and by the degree of inflammation. However, the ability to discriminate subsets and the relevance for routine practice are unclear.	Ib–IIb	72 (63 to 87)
4	Typical symptoms of knee OA are usage-related pain, often worse towards the end of the day, relieved by rest; the feeling of 'giving away'; only mild morning or inactivity stiffness; and impaired function. More persistent rest and night pain may occur in advanced OA. OA symptoms are often episodic or variable in severity and slow to change.	Ib–IIb	76 (64 to 87)
5	In adults aged >40 years with usage-related knee pain, only short-lived morning stiffness, functional limitation and one or more typical examination findings (crepitus, restricted movement, bony enlargement), a confident diagnosis of knee OA can be made without a radiographic examination. This applies even if radiographs appear normal.	Ib	80 (67 to 92)
6	All patients with knee pain should be examined. Findings indicative for knee OA include: crepitus; painful and/or restricted movement; bony enlargement; and absent or modest effusion. Additional features that may be present include: deformity (fixed flexion and/or varus – less commonly valgus); instability; periarticular or joint-line tenderness; and pain on patellofemoral compression.	Ia–III	90 (85 to 95)
7	Red flags (eg, severe local inflammation, erythema, progressive pain unrelated to usage) suggest sepsis, crystals or serious bone pathology. Involvement of other joints may suggest a wide range of alternative diagnoses. Other important considerations are referred pain, ligamentous and meniscal lesions and localised bursitis.	IV	87 (80 to 94)
8	Plain radiography (both knees, weight bearing, semi-flexed PA (MTP) view, plus a lateral and skyline view) is the current 'gold' standard for morphological assessment of knee OA. Classic features are focal joint space narrowing, osteophyte, subchondral bone sclerosis and subchondral 'cysts'. Further imaging modalities (MRI, sonography, scintigraphy) are seldom indicated for diagnosis of OA.	Ib–IIb	83 (71 to 95)
9	Laboratory test on blood, urine or synovial fluid are not required for the diagnosis of knee OA, but may be used to confirm or exclude coexistent inflammatory disease (eg, pyrophosphate crystal deposition, gout, rheumatoid arthritis) in patients with suggestive symptoms or signs.	IIb	86 (78 to 94)
10	If a palpable effusion is present, synovial fluid should be aspirated and analysed to exclude inflammatory disease and to identify urate and calcium pyrophosphate crystals. OA synovial fluid is typically non-inflammatory with <2000 leukocytes/mm ³ ; if specially sought, basic calcium phosphate crystals are often present.	IIb	73 (56 to 89)

LoE, level of evidence (Ia, meta-analysis of cohort studies; Ib, meta-analysis of case-control or cross-sectional studies; IIa, cohort study; IIb, case-control or cross-sectional studies; III, non-comparative descriptive studies; IV, expert opinion); MTP, metatarsophalangeal joint; OA, osteoarthritis; PA, posterior-anterior; SOR, strength of recommendation on visual analogue scale (0–100 mm; 0, not recommended at all; 100, fully recommended).

For hand OA, 10 recommendations were also made (table 7). The 10 recommendations cover a wide range of topics, including risk factors for hand OA, clinical manifestations, subsets, differential diagnosis, imaging and laboratory tests. The diagnosis of hand OA cannot be determined with confidence using a single feature and so several features are required. The probability of a subject having hand OA was 20% when Heberden's nodes alone were present, but this increased to 88% when in addition the subject was over 40 years old, had a family history of nodes and had joint space narrowing in any finger joint.

The radiological definition of OA is widely used in epidemiological studies and in many clinical studies. The most commonly used grading system is that of Kellgren and Lawrence, which is a composite score based on the presence of osteophytes, joint space narrowing, subchondral sclerosis and bony cysts (Kellgren et al, 1963). This system divides OA into five grades (0–4), giving a global score at various joint sites in comparison to a radiographic atlas. A score of 2 or more has traditionally been considered to be a definitive radiographic diagnosis of OA and has been widely used in research. However, Kellgren–Lawrence grade I (doubtful) is more likely to evolve to OA than is grade 0, suggesting that it corresponds to an early disease subgroup (Lachance et al, 2002). Because the Kellgren–Lawrence grading system relies predominantly on osteophyte size to determine OA severity, the atrophic form of OA, which consists mainly of joint space narrowing, is underestimated. Unfortunately, Kellgren–Lawrence grading is characterised by discrepancy with hip or knee pain. MRI, ultrasonography and biochemical markers are not included in any set of criteria yet, but new definitions and criteria for OA based on such approaches are being developed.

Table 7 Diagnosis of hand OA: propositions and strength of recommendation – order according to topic (risk factors, clinical, subsets, differential diagnosis, images and laboratory tests) (Reproduced from Zhang et al, *Ann Rheum Dis* 2009;68:8–17.)

No.	Proposition	LoE	SOR (95% CI)
1	Risk factors for HOA include female sex, increasing age over 40, menopausal status, family history, obesity, higher bone density, greater forearm muscle strength, joint laxity, prior hand injury and occupation or recreation-related usage.	Ib–IIb	69 (54 to 84)
2	Typical symptoms of HOA are pain on usage and only mild morning or inactivity stiffness affecting just one or a few joints at any one time; symptoms are often intermittent and target characteristic sites (DIPJs, PIPJs, thumb base, index and middle MCPJs). With such typical features, a confident clinical diagnosis can be made in adults aged over 40.	IIb	85 (77 to 92)
3	Clinical hallmarks of HOA are Heberden's and Bouchard's nodes and/or bony enlargement with or without deformity (eg, lateral deviation of IPJs, subluxation and adduction of thumb base) affecting characteristic target joints (DIPJs, PIPJs, thumb base, and index and middle MCPJs).	Ib–IV	80 (69 to 90)
4	Functional impairment in hand OA may be as severe as in rheumatoid arthritis. Function should be carefully assessed and monitored using validated outcome measures.	IIb	57 (42 to 73)
5	Patients with polyarticular HOA are at increased risk of knee OA, hip OA and OA at other common target sites (generalised OA) and should be assessed and examined accordingly.	IIa–IIb	77 (62 to 92)
6	Recognised subsets with different risk factors, associations and outcomes (requiring different assessment and management) include IPJ OA (with or without nodes), thumb base OA and erosive OA. Each may be symptomatic or asymptomatic.	IIa–IIb	68 (56 to 79)
7	Erosive HOA targets IPJs and shows radiographic subchondral erosion, which may progress to marked bone and cartilage attrition, instability and bony ankylosis. Typically, it has an abrupt onset, marked pain and functional impairment, inflammatory symptoms and signs (stiffness, soft tissue swelling, erythema, paraesthesia), mildly elevated CRP levels, and a worse outcome than non-erosive IPJ OA.	IIa–IIb	87 (81 to 93)
8	The differential diagnosis for HOA is wide. The commonest conditions to consider are psoriatic arthritis (which may target DIPJs or affect just one ray), rheumatoid arthritis (mainly targeting MCPJs, PIPJs, wrists), gout (which may superimpose on pre-existing HOA), and haemochromatosis (mainly targeting MCPJs, wrists).	Ib–IIb	81 (73 to 89)
9	Plain radiographs provide the gold standard for morphological assessment of HOA. A postero-anterior radiograph of both hands on a single film/field of view is adequate for diagnosis. Classic features are joint space narrowing, osteophyte, subchondral bone sclerosis and subchondral cysts, and subchondral erosion occurs in erosive HOA. Further imaging modalities are seldom indicated for diagnosis.	Ib–IIb	87 (81 to 93)
10	Blood tests are not required for diagnosis of HOA but may be required to exclude coexistent disease. In a patient with HOA who has marked inflammatory symptoms and/or signs, especially involving atypical sites, blood tests should be undertaken to screen for additional inflammatory arthritides.	Ib–IIb	78 (63 to 92)

CRP, C-reactive protein; DIPJ, distal IPJ; HOA, hand osteoarthritis; IPJ, interphalangeal joint; LoE, level of evidence, presented in range upon components assessed; MCPJ, metacarpophalangeal joints; OA, osteoarthritis; PIPJ, proximal IPJ; SOR, strength on recommendation on visual analogue scale (0–100 mm; 0, not recommended at all; 100, fully recommended).

9.2 Primary or secondary OA?

The traditional concept holds that primary OA is defined in the absence of a history of injury or predisposing disease and that the presence of such feature defines secondary OA. The complexity of OA pathogenesis and the ever-growing list of risk factors identified (eg, genetic, biomechanical and environmental) make this division far less obvious. From the clinical perspective, it may be most useful to consider OA as a common outcome of complex processes with different mechanisms that variably contribute to disease. Nevertheless, as some of the aetiologies or risk factors (table 2 and box 1) are amenable to intervention, they should be carefully identified and managed if possible.

Box 1 Aetiologies of secondary osteoarthritis

1. Metabolic

- Crystal-associated arthritis (gout, calcium pyrophosphate dihydrate arthropathy, pseudogout)
- Acromegaly
- Ochronosis
- Haemochromatosis
- Wilson's disease

2. Anatomic

- Slipped femoral epiphysis
- Epiphyseal dysplasias
- Blount's disease
- Legg-Perthe disease
- Congenital dislocation of the hip
- Unequal leg lengths
- Hypermobility syndromes

3. Traumatic

- Major joint trauma
- Fracture through a joint or osteonecrosis
- Joint surgery (eg, meniscectomy)
- Chronic injury (occupational arthropathy)

4. Inflammatory

- Any inflammatory arthropathy
- Septic arthritis

5. Septic arthritis

9.3 OA clinical assessment

The assessment of a patient with OA should include discrete evaluation of pain and function with an emphasis on patient-reported outcomes. This is important since therapeutic decisions, such as prosthetic surgery, depend mainly on this. Evaluation of walking distance without pain or before the need to sit down and the need for external support (i.e., canes) is valuable. The activities of daily living such as climbing stairs and loss of

time from work, and the capacity to perform household chores or recreational activities are also important. Of note, all these data must be interpreted with the age, weight and lifestyle of the patient.

Overall assessment, global pain or disability can also be quantitatively evaluated using simple tools such as a five-point Likert scale (none, mild, moderate, severe, very severe), or on a 100 mm visual analogue scale (VAS). Pain can also be assessed indirectly by estimating the symptomatic treatment required, such as the number of days per week that drugs are required or their consistent dose usage (Constant et al, 1997).

Box 2 Western Ontario and McMaster Universities (WOMAC) composite index

1. Pain subscale (5 questions)

How much pain do you have...

- Walking on a flat surface?
- Going up or down stairs?
- At night while in bed?
- Sitting or lying?
- Standing upright?

2. Stiffness subscale (2 questions)

- How severe is your stiffness after first walking in the morning?
- How severe is your stiffness after sitting, lying down, or resting later in the day?

3. Function subscale (17 questions)

What degree of difficulty do you have with...

- Descending stairs?
- Ascending stairs?
- Rising from sitting?
- Standing?
- Bending to floor?
- Walking on the flat?
- Getting in or out of a car?
- Going shopping?
- Putting on socks or stockings?
- Rising from bed?
- Taking off socks/stockings?
- Lying in bed?
- Getting in and out of the bath?
- Sitting?
- Getting on or off the toilet?
- Heavy domestic duties?
- Light domestic duties?

One of the instruments widely used to assess pain and disability is the Western Ontario and McMaster Universities (WOMAC) composite index (Bellamy et al, 1988) (box 2). It is used mainly for the knee or the hip. Within the WOMAC composite index, pain is evaluated with a VAS or Likert scale in five different situations:

walking on a flat surface, going up and down stairs, at night while in bed, sitting or lying, and standing upright. Functional disability due to knee or hip OA is usually evaluated using the WOMAC function subscale, which is a questionnaire of 17 items related to daily activities, and by the Lequesne functional index (table 8), which is an index including questions related to pain, performance and function impairment (Lequesne et al, 1987).

Table 8 Lequesne algo-functional index

Pain or discomfort	Points
<i>During nocturnal bed rest</i>	0
None or insignificant	1
Only on movement or in certain positions	2
With no movement	
<i>Morning stiffness or regressive pain after rising</i>	0
1 min or less	1
More than 1 but less than 15 min	
<i>After standing for 30 min</i>	0 or 1
<i>While walking</i>	0
None	1
Only after walking some distance	2
After initial walking and increasingly with continued walking	
<i>With prolonged sitting (2 h)</i>	0 or 1
<i>Maximum distance walked (even with pain)</i>	0
Unlimited	1
More than 1 km but limited	2
About 1 km (0.6 mile) in about 15 min	3
500–600 m (1640–2952 ft or 0.31–0.56 miles) in about 8–15 min	4
300–500 m (987–1640 ft)	5
100–300 m (328–985 ft)	6
Less than 100 m (328 ft)	1
With one walking stick or crutch	2
With two walking sticks or crutches	
<i>Day-to-day activities*</i>	0 or 2
Put on socks by bending forward	0 or 2
Pick up an object from the floor	0 or 2
Climb up and down a standard flight of stairs	0 or 2
Get into and out of a car	

0, without difficulty; 1 (or 0.5 or 1.5), with difficulty; 2, unable.

The Knee injury OA Outcome Score (KOOS) was developed as an extension of the WOMAC OA index (Roos et al, 1998a) (<http://www.koos.nu>) and is a 42-item self-administered knee-specific questionnaire. It consists of five subscales (pain, other symptoms, function in daily living, function in sport and recreation, and knee-related quality of life). Standardised answer options are given, and the response to each question is scored from 0 to 4 in Likert boxes. A score of 0 to 100 is calculated for each subscale; 100 is the best result (Roos and Lohmander, 2003). A difference of 10 points is considered to be clinically significant. The Foot and Ankle

Outcome Score (FAOS) and Hip disability and OA Outcome Score (HOOS) are also available (Roos et al, 2001; Nilsson et al, 2003). Short measures of physical function for knee and hip OA are available, derived from KOOS and HOOS (Davis et al, 2008; Perruccio et al, 2008). Recently, the Intermittent and Constant OA Pain (ICOAP) questionnaire for hip and knee OA was developed. The patient's perspective was taken into account in the development of these questionnaires (Hawker et al, 2008; Maillefert et al, 2009). The Short-Form 36 (SF-36) is a generic instrument that can be used to assess health-related quality of life.

Impaired function in hand OA can be assessed in clinical trials using the Functional Index for Hand OA (FIHOA) or the Australian/Canadian OA Hand Index (AUSCAN) (box 3) (Dreiser et al, 2000; Bellamy et al, 2002; Allen et al, 2006). In addition, the AUSCAN, a self-administered questionnaire, also investigates pain and stiffness.

Box 3 Functional Index for Hand OA (FIHOA)

1. Are you able to turn a key in a lock?
2. Are you able to cut meat with a knife?
3. Are you able to cut cloth paper with a pair of scissors?
4. Are you able to lift a full bottle with the hand?
5. Are you able to clench your fist?
6. Are you able to tie a knot?
7. For women: are you able to sew? For men: are you able to use a screwdriver?
8. Are you able to fasten buttons?
9. Are you able to write for a long period of time?
10. Would you accept a handshake without reluctance?

In daily practice, all these tools can be used for clinical assessment, because they contribute to better communication between physicians and between patients and physicians. Their limitation is the time consumption accepted by the clinician. In organised settings, for instance when seeing patients with a confirmed diagnosis in a dedicated clinic, questionnaires can be filled out by the patients before they see the physician, and such tools can then be very useful for patient follow-up. For clinical trials, responder criteria are recommended so that results of changes after treatment can be presented in three symptomatic domains (pain, function and patient's global assessment) preferably as a single variable (Pham et al, 2004). The above-mentioned questionnaires and indexes are commonly used in addition to radiographic outcome measures in clinical trial settings.

9.4 Structural severity assessment

Standard plain radiographs have been extensively used to detect and stage the articular changes of OA. They remain the gold standard in clinical trials, even though this method has many weaknesses such as poor sensitivity and specificity in patients with early OA. Furthermore, there are differences in the interpretation of radiographic signs. Structural progression has not yet been accurately defined, despite the fact that this

feature is essential for evaluating the structural efficacy of treatment. MRI and ultrasonography can be useful tools for investigating alterations of joint structure in the future. The advantage of MRI is that it can be used to study cartilage, subchondral bone and synovial tissue simultaneously. The obvious disadvantage is the greater complexity of the assessment and the standardisation of protocols between centres. A variety of grading systems has been proposed with some specificity according to the site. They include several items such as joint space narrowing, sclerosis and osteophytes (Altman et al, 1987). Joint space narrowing seems to be the most important feature for defining progression of hip or knee OA (Ornetti et al, 2009). To attain sufficient sensitivity in change over time, standardised acquisition of radiographs is warranted.

The Kellgren–Lawrence grading system remains the most commonly used method (see above) for assessing the severity of structural abnormalities. The OARSI grading system separates osteophyte formation and joint space narrowing with semi-quantitative scales supported by the OARSI atlas (Altman and Gold, 2007) (i.e., minimal, moderate, severe joint space narrowing).

9.5 Biological markers

Many laboratories are working to find surrogate biomarkers that can reveal a correlation between joint space narrowing and the concentration of specific biological parameters in blood or urine (Garnero, 2002). These include components of matrix proteins including several collagens and cross-linked derivative peptides and matrix metalloproteinases. There is still no consensus about the optimal biomarkers and, to date, there is no indication to apply them in daily practice.

9.6 Time to total joint replacement

Total joint replacement can be considered as the best endpoint for clinical trials evaluating disease-modifying OA drugs. However, many parameters other than the severity of the disease itself influence the decision for surgery, including socio-economic factors, access to health services, and the age and BMI of the patient (Escalante et al, 2000; March et al, 2002; Fielden et al, 2005; Steel et al, 2006). An attempt to develop a composite index including pain and functional disability corresponding to an indication for total joint replacement (TJR) in hip and knee OA was unsuccessful, since it did not discriminate between those who were and those who were not considered to need TJR by the orthopaedic surgeon (Gossec et al, 2011*).

SUMMARY POINTS

- Osteoarthritis (OA) is the most common joint disorder representing a socio-economic burden.
- The natural history of OA varies widely according to the affected joint and the OA subtype (ie, erosive or non-erosive OA).
- Pain on usage clearly related to activity is the hallmark of OA symptoms.
- Risk factors are obesity, female sex, oestrogen deficiency, ageing, family history, active subarticular bone remodelling, joint laxity, playing sports or occupational joint overload, prior injury with damaged ligaments and meniscectomy and misalignment.
- The pathological features of the osteoarthritic joint are erosion of the articular cartilage, subchondral sclerosis, osteophyte formation, synovitis and alterations of the joint capsule.
- OA is characterised by an imbalance between catabolism and anabolism of the extracellular cartilage matrix.
- Soluble key mediators leading to cartilage disruption are the matrix metalloproteinase family (aggrecanases) and collagenases responsible for breakdown of proteoglycans and collagen.
- Inflammation involving cytokines such as IL-1, IL-6 and TNF α is increasingly recognised as an important factor in OA development and progression.
- Adipocytokines are soluble mediators involved in the degradation of cartilage that can account for OA in non-weight bearing joints in obese patients.
- Low-grade synovitis is a crucial factor in the pathogenesis of OA, producing proinflammatory cytokines and a vicious cycle between cartilage degradation and synovial inflammation.
- Plain radiographs are the gold standard for diagnosis and are useful to establish the knee joint compartment involved as well as the degree of disease progression, although the radiographic findings correlate poorly with pain severity.

Osteoarthritis: pathogenesis, clinical aspects and diagnosis

Augustin Latourte, Pascal Richette, Rik Lories

A previous version was co-authored by Rik Lories, Barbara Neerinckx, Francis Berenbaum, Rani Liu, Margreet Kloppenburg, Jérémie Sellam, Gabriel Herrero-Beaumont

IN-DEPTH DISCUSSION I

Erosive osteoarthritis (OA)

Definition

Erosive OA is regarded as a subset of hand OA. The term ‘erosive OA’ was first used by Peter et al. in 1966 to describe 6 women with OA in interphalangeal joints (IPJs) with the presence of inflammation and development of erosive and osteoarthritic signs on radiographs (Peter et al, 1966). Although earlier, Kellgren and Crain (Kellgren and Moore, 1952; Crain, 1961) had already described the clinical and radiographic features. Erosive OA is a radiographic subset of OA that is based on the presence of central erosions and collapse of the subchondral bone plate. Erosions can be detected in several hand joints, such as the IPJs and the first carpometacarpal joint (CMCJ), but also in the knees, the shoulders, and the metatarso-phalangeal joints (Zhang et al, 2002; van Saasse et al, 1989). However, the term “erosive OA” specifically relates to hand OA with erosions in the IPJs. Subchondral erosions in other joint sites, such as the knees and the first CMCJ, seem not to be related to erosions in the IPJs (Haugen et al, 2011; Kwok et al, 2011).

Prevalence

The prevalence of erosive OA, when compared to non-erosive hand OA is relatively low. In large-scale population-based studies the prevalence of erosive OA among participants with symptomatic hand OA was around 10% (Kwok et al, 2011; Haugen et al, 2011). Erosive OA tends to be more prevalent in females than in males. The prevalence of erosions in first CMCJ (thumb base) is lower than in IPJs, and the co-occurrence of erosions in both sites at the same time is relatively rare (Kwok et al, 2014).

Aetiology

Whether erosive OA comprises a separate disease entity with specific risk factors and pathogenesis or a more severe stage of hand OA is until now unclear (Zhang et al, 2009). Several underlying mechanisms have been suggested to be implicated in erosive OA, both systemic and local ones. The role for underlying systemic mechanisms is supported by the finding that new erosions develop especially in patients who already had erosions (Bijsterbosch et al, 2011).

A potential systemic factor is inflammation. The clear signs of inflammation present in some forms of hand OA lead Ehrlich in 1972 to the use of the term ‘inflammatory OA’ for the subset that is now referred to as erosive OA. He described this as a “nodose form of arthritis which begins abruptly and painfully with dramatic redness overlying the involved joints” (Ehrlich et al, 1972). The role of inflammation was further demonstrated by histology of synovial biopsies of erosive DIPJs and PIPJs in an inflammatory stage, showing intense proliferative synovitis indistinguishable from rheumatoid arthritis (Peter et al, 1966). In hand OA, soft tissue swelling is associated with erosive progression (Meersseman et al, 2015). The higher levels of high-sensitivity C-reactive protein in patients with erosive OA compared to patients with non-erosive OA are in line with these

observations (Punzi et al, 2005). During the last few years, ultrasound studies have been performed and reveal that power Doppler signal, as signal of active inflammation, is frequently seen in patients with erosive OA (Vlychou et al, 2009; Kortekaas et al, 2015), especially in the phase that erosive activity is taking place (Wittoek et al, 2010). Moreover, synovial inflammation, as assessed by ultrasound or MRI, may be an important predictor of incident erosions in hand OA (Mancarella et al, 2015; Kortekaas et al, 2016; Haugen et al, 2016).

Genetic predisposition could play a role in the pathogenesis of erosive OA (Stecher et al, 1953). In a sibling pair study, familial aggregation for evolution of erosions was seen, suggesting that heritable factors play a role. Several genetic factors have been reported to be associated with erosive OA. Remarkably, genetic factors were found to be associated rather with erosive OA, than with non-erosive hand OA. However, before definite conclusions can be drawn, further replication studies have to be performed.

The role of metabolic comorbidities and cardiovascular risk factors in the pathogenesis of erosive OA is currently debated (Marshall et al, 2015; Magnusson et al, 2015; Stand et al, 2017). Local joint factors, such as joint pain and joint space narrowing, can also play a role in erosive evolution (Bijsterbosch et al, 2011).

Imaging

Established criteria for erosive OA do not exist. Erosions on radiographs can be defined by different scoring methods (Altman and Gold, 2007; Kallman et al, 1989; Verbruggen and Veys, 1996), but whether one or more erosive joints have to be present to define erosive disease is not yet established (Gazeley et al, 2017).

Radiographic features of erosive OA are central subchondral erosions, joint space narrowing, collapse of the subchondral bone and subchondral sclerosis (Kidd and Peter, 1966; Martel et al, 1980) (Figure 1). The central erosions can appear like typical 'sea-gull wing' or 'saw-tooth lesions' (Martel et al, 1989). Whereas both the OARSI method and the method developed by Kallman et al. score the presence or absence of a central/subchondral erosion or collapse in the interphalangeal joints, the Verbruggen-Veys method is based on scoring osteoarthritic joints in progressive, consecutive phases (Verbruggen and Veys, 1996). Five anatomical phases are distinguished, being the normal (N), stationary (S), joint space loss (J), erosive (E) and remodelled (R) phase. The sequence of evolution from N to S to J to E to R phase is proposed to reflect the natural history of erosive OA (Verbruggen and Veys, 1996). Only the OARSI method displays an example to score erosions in the first CMCJ (Altman and Gold, 2007).

Recently, ultrasound (US) and MRI are available to detect erosions. Erosions on US are defined as a cortical break seen in both longitudinal and transverse scans. First, US was shown to be less sensitive for erosions than radiographs (Iagnocco et al, 2005) and erosions were therefore not included in a US scoring system for hand OA (Keen et al, 2008). However, in recent US studies erosions could be detected, and US was even more

sensitive than radiography (Vlychou et al, 2009; Wittoek et al, 2010; Wittoek et al, 2011). Moreover, US was validated with MRI as a reference method (percentage of agreement between MRI and US for erosions was 78%, kappa= 0.55). Grainger et al. reported that erosions, especially marginal erosions, in patients with hand OA were more often present on MRI than on radiography (Grainger et al, 2007). Marginal erosions resembled those seen in inflammatory arthritides. Using MRI, 80% of joints examined showed one or more erosions compared with 40% using radiographs. The characterization of erosions on MRI and the association between erosions and other structural abnormalities, such as bone marrow lesions, will be facilitated by a recently developed scoring method (Haugen et al, 2011; Haugen et al, 2014).

Figure 1: Erosive osteoarthritis in multiple DIPJ and PIPJs, with signs of osteophytes

Clinical burden

Erosive OA is considered to have a higher clinical burden and worse outcome than non-erosive hand OA (Kwok et al, 2013). The structural damage that can affect the IPJs can eventually lead to instability of the joint and ankylosis (Patrick et al, 1989). As a consequence, people with erosive hand OA have three times more pain and two-and-half times more hand disability than persons with non-erosive hand OA. However, research in detail revealed that the high clinical burden does not only depend on the presence of erosions. Patients with erosive OA also have more nodes, which are determinants of clinical outcome as well. Taking the number of nodes into account, hand mobility and patient satisfaction regarding function and aesthetics are worse in patients with erosive OA compared to patients with non-erosive hand OA. Although, pain, disability, mobility and grip strength are not. In a French study, aesthetic discomfort, which was especially reported by women with erosive OA with a high clinical burden, was also associated with depression, anxiety and poor health related quality of life (Hodkinson et al, 2011).

IN-DEPTH DISCUSSION II

Models of osteoarthritis

Models of osteoarthritis: A more extensive discussion of this topic can be found in Thysen S, Luyten FP, Lories RJ. Targets, models and challenges in osteoarthritis research. Dis Model Mech. 2015 Jan;8(1):17-30. doi: 10.1242/dmm.016881.

In vivo models aim to recapitulate OA disease processes and associated lesions. Understanding mechanisms of disease and assessing the clinical response to potential therapies are important conditions for the translation of genetic or *in vitro* data towards therapy in patients. Animal models of OA include naturally occurring OA by (accelerated) aging, transgenic animals, as well as surgically or chemically induced models. Unfortunately, there is no animal model that completely reproduces the signs and symptoms of human OA, a group of diseases with very different presentations. Each model and species used has distinct advantages and disadvantages and the impact of preclinical research depends largely on the choice for the most appropriate preclinical model of OA.

For example, the spontaneous development of OA in transgenic animals can give very useful information about the effect of a gene of interest. Long term strategies such as MMP inhibitors or nutraceuticals may also be studied in such long-term set-ups. In contrast, short-term surgical models show less variability and may be more cost-effective. The relative disadvantage is that these induced models may reflect more post-traumatic OA and not be entirely representative of spontaneous developing human OA that is typically a fairly slow process. In general, small animals (mice, rats, rabbits and guinea pigs) are most often used in the search for specific disease mechanisms and in initial drug screenings for reasons of cost-effectiveness, ease of handling and housing and opportunity for genetic manipulations. Large animal models show more similarity to humans based on their cartilage morphology, joint anatomy and biomechanics and provide therefore more clinically relevant data. However, these models are higher in cost and have heightened ethical concerns and a poor genetic characterization. Nevertheless, they are a crucial and necessary step in the safe and cost-effective development of new therapies. Most models specifically assess the knee joint as this is the predominant joint for natural OA to occur and it is sufficiently large in all animal models for intra-articular manipulations.

Outcome measures

The assessment of joint damage, in particular cartilage loss is an essential part of the animal model discovery or preclinical work. Pioneering work in the histopathologic assessment of OA was established by Collins (Collins, 1939), who based his grading system (Grades I-IV) on the degree of fibrillation of articular cartilage. In 1971, Mankin et al. (Mankin, 1971) developed a microscopic Histologic Histochemical Grading system (HHGS) (14 point scoring system) based on a combination of cellular changes, extracellular matrix staining with Safranin O and structural changes. Although these scoring systems are still used, they have many limitations, particularly in the assessment of early OA. The OARSI histopathology initiative developed a standardized scoring system for the most important small and large animal models that assesses joint degeneration by

‘staging’ and ‘grading’ systems. Ideally, macroscopic and microscopic evaluation of OA requires a more holistic approach given the importance of the non-cartilaginous structures for the disease process. The OARSI histopathology initiative fills in the shortcomings from previous scoring systems and provides additional scoring parameters to explore alterations in the synovium, subchondral bone, menisci, tendons and ligaments (Cook et al., 2010; Gerwin et al., 2010; Glasson et al., 2010; Kraus et al., 2010; Lavery et al., 2010; Little et al., 2010; McIlwraith et al., 2010).

As an alternative for the time-consuming and tissue-destructive histopathology, non-invasive imaging techniques such as MRI and microCT are increasingly used in animal studies. Non-invasive in vivo imaging can be used for longitudinal follow-up in the same animal to monitor the disease progress and treatment monitoring in drug trials. Standard clinical MRI (1.5 and 3T) is being used in large animal models (dogs, goats/sheep, horses) (Galindo-Zamora et al., 2013; Ley et al., 2013). Rodents and rabbits are too small to undergo standard in vivo MRI. Recently, high-resolution micro-MRI (>7T) has been performed on rats and rabbits to monitor cartilage lesions of surgically induced OA (Batiste et al., 2004; Goebel et al., 2010). This area of imaging needs further optimization and is challenging because, among other reasons, imaging of small rodent joint requires specific magnetic coils. μ CT is preferably used for high-resolution imaging of bone architecture alterations. Due to its low soft-tissue contrast, direct imaging of the cartilage is impossible. Contrast agents such as ioxaglate or hexabrix permit visualization of cartilage.

Small animal models

Mouse

Mice are widely used as an animal model because of the easy management, low costs, and the availability of genetically modified animals. Spontaneous OA occurs in aged C57Bl/6 and BALB/c mice (Stoop et al., 1999), but is much more pronounced in the STR/ort mouse strains and therefore this strain is more often used in screening studies (Mason et al., 2001). The possibility to induce genetic modifications (transgenic, knock-out and knock-in, inducible, tissue specific) made the mouse model an extremely useful tool for replicating genetic defects and elucidating the molecular pathogenesis of OA.

Acute enzymatic-, chemically- or inflammation-induced OA models (e.g. intra-articular injection of collagenase (van der Kraan et al., 1989), methylated bovine serum albumin (mBSA) (Stanton et al., 2005) and papain (van der Kraan et al., 1989)) and destructive surgical models (e.g. (partial) medial meniscectomy ((P)MM), medial collateral ligament transection (MCLT) and anterior cruciate ligament transection (ACLT) (Clements et al., 2003)) lead to severe OA pathology in mice (Glasson et al., 2007). Currently, the Destabilization of the Medial Meniscus (DMM) surgical model is frequently used as a clinically relevant OA model. Transection of the medial meniscotibial ligament leads to altered mechanical loading and induces cartilage damage that more closely resembles some aspects of the slowly progressive human disease (Glasson et al., 2007).

When studying the effects of biomechanics in OA, the mouse is not an ideal model due to its small size compared to humans. Additionally, mouse knee cartilage has relatively few cell layers and less of a zonal tissue organization when compared to the larger species, which make it difficult to induce small lesions that extend slowly through the different depths of the non-calcified cartilage over-time (Glasson et al., 2010).

Rat

Rat models are relatively similar to mouse models, as they are relatively inexpensive and easy to house and handle. Natural occurring OA is extremely uncommon and transgenic models of OA are not yet available, but the technology to generate transgenic overexpression and knockout rats is increasingly used in other fields (Huang et al., 2011). Consequently, chemically- (e.g. i.a. injection of iodoacetate (Guzman et al., 2003)) and surgically induced (e.g. medial meniscal tear (MMT) or ACLT (Hayami et al., 2006)) models are frequently performed in rats. The thicker cartilage with zonal structure makes direct surgically-created partial- and full-thickness cartilage lesions possible (Gerwin et al., 2010). Rats are therefore attractive animal models to study cartilage repair by gene therapy, stem cell transplantation, chondrocyte implantation and local growth factor stimulation. Rat models have also been used for the assessment of OA-related pain (Bove et al., 2006) and to study the outcome of novel pain therapies (Ahmed et al., 2012; Cowart et al., 2012; Schuelert and McDougall, 2006).

Rabbit

Like rodents, rabbits are easy to handle and have relatively low housing costs. The rabbit knee joint has some anatomical similarities with the human knee. However, the biomechanics are different and therefore, the rabbit is less suitable for functional studies. The rabbit is used frequently in cartilage regeneration experiments, as large quantities of cells can be extracted from rabbit tissues. A disadvantage is that young rabbits have a high potential for spontaneous healing of cartilage or osteochondral defects. Articular cartilage of rabbit femorotibial joints matures at approximately 3 months (Lavery et al., 2010).

Guinea pig

The spontaneous occurring OA in the Hartley guinea pig is a frequently used model because it displays progressive degenerative changes that closely resemble the development of OA in humans. The spontaneous guinea pig OA model has clear advantages to large animals because the time to reach skeletal maturity is much shorter (Kraus et al., 2010).

Large animal models

A major advantage of using large animals is that their macroscopic and microscopic anatomy is similar to the human situation and the opportunity to undertake topographical analysis of joint cartilage by arthroscopy and

serial aspiration of synovial fluid for biomarker analysis. A disadvantage is that histology of large animal joints is more difficult because the whole joint can't be captured on a single microscopic section.

The canine model is a very good translational model for biomarker studies. Most frequently used models in dog are the ACLT model (a.k.a. Pond/Nuki model) (Kuroki et al., 2011) and the groove model (Intema et al., 2008). Additionally, dogs, like horses (McIlwraith et al., 2010), are also prone to develop natural occurring osteoarthritis with overuse or age and undergo similar treatments as humans (Cook et al., 2010; Tirgari and Vaughan, 1975).

Goats and sheep, however, do not appear to develop spontaneous OA (Little et al., 2010). Another disadvantage is that these animals are ruminants and so the bioavailability of oral therapies needs to be tested before starting animal studies. Surgically-induced models for goats and sheep are partial or total meniscectomy. The ACLT model only induces very mild cartilage damage (Little et al., 2010).

Osteoarthritis: treatment

John Edwards, Zoe Paskins, Krysia Dziedzic

A previous version was coauthored by Zoe Paskins, Krysia Dziedzic, Burkhard Leeb

LEARNING OBJECTIVES

- Define the principles of evidence-based practice and the three main sources of evidence that need to be considered
- Specify the objectives of management of patients with osteoarthritis (OA)
- Apply the principles of management of patients with OA
- Apply three core non-pharmacological aspects of management that should be considered in every patient with OA and justify their central role in management
- Justify and apply an initial trial of simple safe analgesia for pain control
- Select appropriate adjunctive treatments from at least 10 recommended treatment options that may be considered for patients with OA
- Discuss the indications, benefits and side effects of intra-articular injection of glucocorticoid for symptomatic OA
- Specify the benefits and principles of strengthening and aerobic exercise for patients with large joint OA
- Critically evaluate the research evidence for management of OA
- Review quality care for OA
- Consider models of OA care
- Consider the role of the multidisciplinary team in primary care
- Consider the role of the rheumatologist in the care of patients with OA

1 Introduction

Osteoarthritis (OA) is by far the most prevalent joint disease and a leading cause of disability in older adults. Unsurprisingly, OA-related pain and limitation of activity is one of the most common causes for adult consultation in primary care. In recent years a number of international evidence-based clinical practice (EBP) recommendations for OA have been published to help guide clinical decision making (Jordan et al., 2003; Zhang et al., 2005*; Zhang et al., 2007a*; Zhang et al., 2007b*; Zhang et al., 2008; Zhang et al., 2010*; NICE, 2008*; NICE, 2014a*; Fernandes et al., 2013*; McAlindon et al., 2014*). However, there is evidence that OA is given a low priority by health professionals and patients and that recommendations are not translated into practice. This overview will address the following areas:

- the principles of EBP and the level of agreement between recent guidelines developed by different methodologies
- the management objectives for OA
- the agreed core set of treatments that everyone with OA should receive
- the other recommended treatment options that are available for incorporation into the central management plan for patients with OA and the possibility of using structure-modifying drugs
- the caveats and omissions with respect to the clinical research base for management of OA
- the indicators of quality care in OA
- the rheumatologist's role in OA management.

2 Evidence-based recommendations for OA

The philosophy of EBP is to make rational clinical decisions in light of available evidence and to integrate the best research evidence with clinical expertise and patient values (Sackett, 2000). The three main forms of evidence for clinical management that need to be examined critically and with common sense are: (1) research (mainly clinical trials and observational studies); (2) expert practitioner experience and opinion; and (3) patient acceptability, experience and opinion. Misguidedly, many people consider EBP to be focused predominantly on research evidence, but all three are equally weighted (figure 1). It is only when all three concur that we can truly approach 'best practice' (Sackett, 2000).

Figure 1 The three types of evidence to consider for evidence-based management. All three are equally weighted.

There is an accepted hierarchy with respect to research evidence for the efficacy of clinical treatments, the highest level being meta-analysis of randomised controlled trials (RCTs) (box 1). For uncommon or rare side effects of treatments, however, RCTs are less sensitive than large observational studies, which may be considered a higher category in this respect.

Box 1 Level of evidence according to source

Category of evidence from:

- Ia: Meta-analysis of randomised controlled trials (RCTs)
- Ib: RCT
- IIa: Controlled study without randomisation
- IIb: Quasi-experimental study
- III: Non-experimental descriptive studies, such as comparative, correlation and case–control studies
- IV: Expert committee reports or opinion or clinical experience of respected authorities, or both

For some interventions, especially surgery and physical interventions, there may be very few or even no RCTs to examine. This may result from ethical issues (e.g., inability to undertake a sham joint replacement) or the impossibility of blinding an intervention (e.g., spa therapy). Although this may result in a low level of research evidence, if observational studies and expert and patient opinion strongly support the use of such interventions (e.g., joint replacement surgery), these can still be strongly recommended. Recommendation of a treatment is not just based on efficacy and safety. Cost, the logistics of delivery, and patient acceptability all need consideration. Such multifaceted decision-making may result in different guideline groups giving different strengths of recommendation for the same treatment, especially when they vary in terms of

composition (specialists, general practitioners, allied health practitioners, patients, etc) and the methodology employed to derive consensus. Therefore all types of evidence, including EBP guidelines, need to be examined with care and common sense. Estimation of efficacy in OA clinical trials is usually presented as effect size (ES) and 95% CI in comparison to placebo (or active control) for outcomes such as pain relief and improvement in function. The effect size is the standardised mean difference: the mean difference between treatment and control divided by the standard deviation of the difference. It has no units and is comparable across interventions. Clinically, an ES of 0.2 is considered small, 0.5 is moderate, and 0.8 is large (Zhang et al., 2005*; Zhang et al., 2007a*).

EULAR has produced separate EBP recommendations (combining both research evidence and expert opinion) for the management of knee OA (Jordan et al., 2003), hip OA (Zhang et al., 2005*) and hand OA (Zhang et al., 2007a*) in recognition that treatment options may differ according to the joint affected. The Osteoarthritis Research Society International (OARSI) has produced similar recommendations for hip and knee OA (Zhang et al., 2007b*; Zhang et al., 2008*; Zhang et al., 2010*; McAlindon et al., 2014*). Most recently, the National Institute for Health and Care Excellence (NICE) in collaboration with the Royal College of Physicians UK has published guidelines for OA in general, taking into account multisite OA (NICE, 2008*; NICE, 2014a*). The Ottawa panel has guidelines also for the management of hip (exercise) and knee OA (Brosseau et al., 2016, 2017a, 2017b, 2017c). EULAR has also published recommendations for non-pharmacological therapies (Fernandes et al., 2013*). Although there are differences in detail between these guidelines, as with previous guidelines published worldwide, there is good overall agreement on the treatment objectives, the principles of management, and the selection of main treatment options.

2.1 Knowledge mobilisation

There is evidence that patients do not receive treatments with proven clinical and cost effectiveness despite being recommended by international guidelines, and there is large variation in practice (Porcheret et al., 2007a; Porcheret et al., 2007b, Hagen et al., 2016). Healthcare professionals often feel that they have little to offer in consultations for OA. Patients want their condition to be taken seriously, but in routine consultations in primary care there is often limited time to address joint pain. For example, written information is a core requirement of a consultation for OA (NICE, 2014a*) and yet in usual practice only a small percentage of patients consulting their general practitioner (GP) will have a record of having received this. In recent years it has been recognised that in order to bridge the gap between evidence and quality clinical care, something else needs to happen. Different terms have been used to describe this activity, such as knowledge brokering, knowledge transfer, knowledge exchange and knowledge mobilisation. Knowing the evidence is not the same as using it in day-to-day consultations. The following sections reflect current recommendations and guidelines, although important differences in advice will be mentioned, and suggest ways in which they can be used in clinical practice.

3 Management objectives

The agreed objectives are:

- Patient education and information access
- Pain relief
- Optimisation of function
- Beneficial modification of the OA process.

4 Management principles

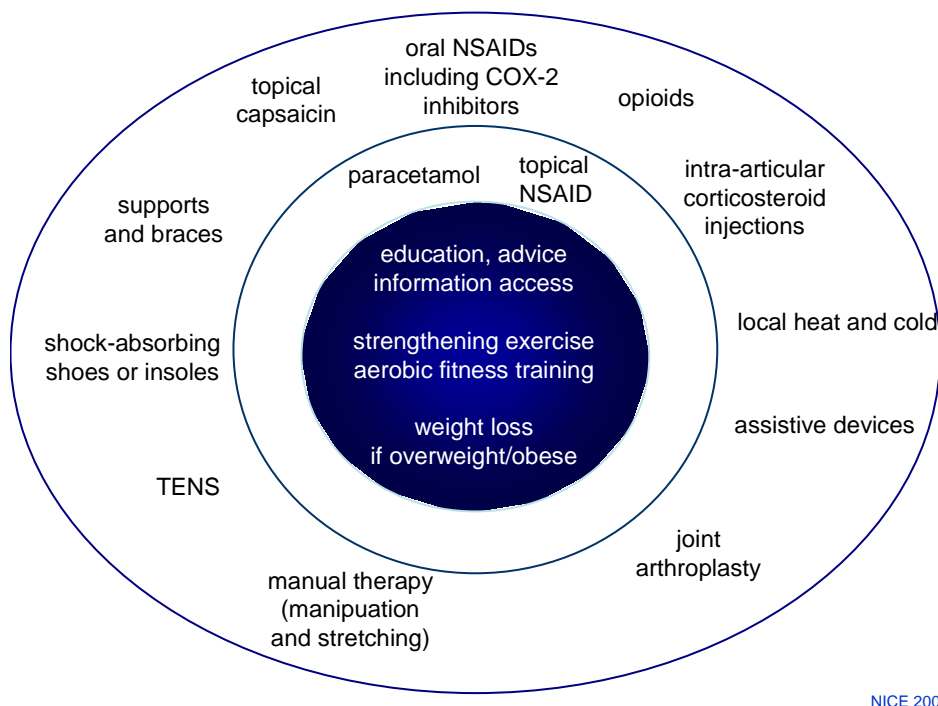

Although there is widespread expert consensus for the key principles of management emphasised in this section, guidelines do diverge in some respects (Nelson et al., 2014). Furthermore, the research evidence to support the management principles is often derived from relatively short-term studies that cannot necessarily reliably inform the ongoing management of a long-term condition (LTC). Management needs to be individualised and patient centred. This is only possible after a thorough, holistic assessment and competent examination. Making, giving and explaining the diagnosis in positive terms is a valuable starting point (Porcheret et al., 2014). Numerous factors influence treatment selection—for example, OA-related factors such as the joint involved, whether more than one joint is affected, the degree of structural damage, and the level of pain intensity. Person-specific factors, such as age, required daily activities (occupation, leisure), patient expectations, number of joints affected and perceptions of OA all modify the approach that is taken.

OA often exists with comorbidity, such as cardiovascular and metabolic diseases (Violan et al., 2014). Consequently, as well as the development of a shared management plan to manage OA, attention to concurrent medication is important. Such comorbidity may influence treatment selection for OA. For example, cardiovascular or renal disease might prevent the use of a particular modality such as a non-steroidal anti-inflammatory drug (NSAID)/coxib (COX-2 selective inhibitor). Anxiety and depression often co-exist with OA (Stubbs et al., 2016) but may go unrecognised in primary care (Memel et al., 2010). Importantly, however, recognition and treatment of comorbidity such as non-restorative sleep or depression, can alleviate the symptoms of OA and reduce the need for analgesia (Fernandes et al., 2013*).

There is a wide selection of treatment options for OA. However, except for intra-articular (IA) glucocorticoid or surgery, the effect sizes of the majority of OA treatments are only modest. Therefore, successful management may require the use of multiple components, both non-pharmacological and pharmacological, rather than a monotherapeutic approach. Evidence for packages of care per se is limited; furthermore, for sites such as the foot there is a paucity of evidence for specific approaches despite high prevalence estimates (Roddy et al.,

2013). Management should always contain the core elements of education and information access, exercise, and reduction of adverse mechanical factors (e.g., weight loss if overweight), together with any adjuncts that are thought appropriate. Such a 'core-plus option' approach has been emphasised, particularly by NICE (2008*) (figure 2).

Figure 2 The National Institute for Health and Care Excellence concept of OA treatment: the central core treatments every patient with osteoarthritis should receive. Additionally, treatments from the middle and outer circle should be selected for the individual patient according to manifestation, severity and functional limitations as well as the time course of disease (NICE, 2008*). *NICE highlighted that paracetamol is less effective than previously considered. COX-2, cyclo-oxygenase 2; NSAID, non-steroidal anti-inflammatory drug; TENS, transcutaneous electrical nerve stimulation. (Source: NICE, 2014a*, <http://www.nice.org.uk>)

NICE 2008

For pain control, an additive rather than substitutive approach is advised. Where no benefit is experienced from a particular type of agent, it should be discontinued to avoid unnecessary polypharmacy. Otherwise, if the first option analgesic gives some relief but is insufficient, then a second agent with a different method of action is added (e.g., a topical NSAID could be added to oral paracetamol (acetaminophen)). If this is still insufficient, then a third agent (e.g., topical capsaicin or oral opioid) and eventually a fourth agent may be added. Such an approach recognises the complex nature of pain processing and the relatively modest effect of any individual pharmacological agent used as monotherapy for chronic pain. In case of improvement, therapy may be reduced in the reverse manner.

After initiation of management, the patient should be reassessed to judge the effectiveness of the plan, and the treatments modified or altered according to the degree of success obtained. This has been highlighted by the recent NICE 2014 update (NICE, 2014a) and supplemented by the NICE Quality Standards (NICE, 2015)

which suggests that patients should be offered an annual review for their osteoarthritis if they have more than one joint affected, comorbidities, troublesome joint pain, or are taking medication for their joint pain.

Consensus shows that review of self-management plans, pain relief and analgesia are considered important by patients, GPs, allied health professionals and nurses (Finney et al., 2013; Porcheret et al., 2013).

The non-specific beneficial effects of treatment should not be under-rated (figure 3). The magnitude of such non-specific (placebo) effects for pain relief in RCTs is far greater than the additional effect obtained by individual drugs such as oral or topical NSAIDs, opioids or nutraceuticals (Zhang et al., 2008). The patient will particularly capitalise on these effects if they are given a thorough assessment by an interested practitioner, if positive messages are reinforced, and if they are reassessed to determine the outcome (Doherty and Dieppe, 2009). Although non-specific effects are considered a major hindrance in RCTs, they are an integral and inevitable component of best clinical practice (Doherty and Dieppe, 2009).

Figure 3 Thorough patient assessment and a positive practitioner–patient encounter. Patient consent obtained.

5 Core treatments to consider for every patient with OA

With an ageing population and increasing risk factors for poorer health such as obesity and reduced physical activity, musculoskeletal conditions such as osteoarthritis will be the main cause of physical disability in older adults. Support for self-management is therefore a priority and the use of core treatment in the management of OA is a key implementation objective. Patients may prefer non-pharmacological approaches and support for self-management over analgesia, but healthcare professionals feel uncertain about and lack confidence in giving such interventions (Paskins et al., 2014).

The core approaches include: access to written information and advice; support for self-management; healthy eating and maintenance of a healthy weight; and advice on exercise and physical activity. These core management principles for OA are the same as those for other LTCs and the knowledge and skills for delivering these key approaches are transferable across a range of LTCs. They may be supplemented with simple analgesia and joint protection techniques.

5.1 Education and information access

It is a professional responsibility to inform patients of their diagnosis and prognosis, to explain tests, and to discuss in detail the advantages and disadvantages of treatment options. This enhances understanding of OA and its management, and counters misconceptions—for example, that OA inevitably progresses and cannot be treated. In addition, access to such information beneficially influences outcome and can be regarded as treatment (figure 4). When studied in OA, access to information has been shown to reduce pain and disability, improve self-efficacy and coping skills, and reduce the frequency of primary care consultation and (in the US system) health costs. It is unclear how this works but it is not only explained by better adherence to other aspects of management like regular exercise. Educational techniques and motivational interviewing can be effective, for example individualised education packages, regular telephone calls, group education, patient coping skills, and spouse-assisted coping skills training. Education does not necessarily require therapist contact but can also use written literature, videos or internet tools. Information sharing and reinforcement should be an ongoing, integral part of management rather than a single event at time of presentation. Information written by patients and healthcare professionals for patients has been shown to be beneficial (Grime and Dudley, 2014).

Figure 4 Positive benefits from information concerning osteoarthritis and its management. Patient consent obtained.

5.2 Advice on exercise and activity

Joints are built to move, and the health of all integral components of the joint depends on regular movement. If a joint is compromised by OA, it is even more important to maintain movement. Two types of exercise can reduce pain and disability long-term and both should be prescribed to anyone with large joint OA, irrespective of age: (1) aerobic exercise (fitness training) and increased activity which improves wellbeing, encourages restorative (delta) sleep and benefits common comorbidities such as obesity, diabetes, chronic heart failure and hypertension; and (2) local neuromuscular training, strengthening, and range of motion exercises for quadriceps and gluteal muscles (figure 5) (Fernandes et al., 2013*). This can greatly improve the detrimental physiological accompaniments of large joint OA, specifically reduced muscle strength, reduced knee proprioception, impaired standing balance, and increased tendency to fall. Such benefits are modest but long lasting if adherence is maintained, giving effect sizes (ES), for example, of 0.39 (95% CI 0.30,0.47) for pain relief and 0.31 (95% CI 0.23,0.39) for functional improvement (Fernandes et al., 2013*). Cochrane reviews of exercise in hip and knee OA identified maintenance of the benefits of exercise on pain and function for two to six months after exercise trial treatment ended, though at a lower effect sizes than during the trial periods (Fransen et al., 2014, 2015). The American College of Rheumatology (ACR) 2012 recommendations for the management of knee OA and hip OA also include aquatic exercises, medially-directed patellar taping, manual therapy, tai chi and psychosocial interventions (Hochberg et al., 2012*). A network meta-analysis comparing different packages of exercises for lower limb OA, predominantly knee OA, demonstrated that combinations of exercise to increase strength, flexibility and aerobic capacity are likely to be the most clinically effective (Uthman et al., 2013). In a recent study, hand exercises delivered in classes by occupational therapists were found to be cost-effective (Oppong et al., 2014), and a systematic review of benefits of hand exercise for OA identified low- to moderate-quality evidence of small-to-moderate beneficial effects on pain (ES 0.27), function (ES 0.28), and stiffness (ES 0.36) (Østerås et al., 2017).

Patients should be advised to balance activity and rest, breaking up long periods of activity (such as shopping, housework and gardening) with frequent, short rest periods—so-called ‘pacing’ of activities. Although this means that specific physical tasks take longer to do, they are more likely to be completed successfully and with less mechanically-induced pain as a result. Patients should be informed that the physical training should be done on a continuous, regular basis.

Figure 5 Simple initial quadriceps strengthening exercise (straight leg raise) being taught to a patient with knee osteoarthritis. Patient consent obtained.

5.3 Reduction of adverse mechanical factors

Obesity is a common comorbidity and an important modifiable risk factor for knee OA, and to a lesser extent hip and hand OA. The principles of education about weight management are detailed in the recent EULAR recommendations (Fernandes et al., 2013*). There are limited numbers of RCTs of weight loss in obese/overweight patients with large joint OA, but these show clear improvement in function, and modest improvements in pain in those who successfully lose weight. Weight loss is advised for many other health reasons and reduction in obesity has obvious face validity with respect to both primary and secondary prevention of knee and hip OA (figure 6). Successful weight loss programmes recommend an individualised programme that contains: frequent self-monitoring; both diet and exercise; regular eating (three times daily); good food variety but reduced portion size; low (saturated) fat and sugar and high fruit and vegetable content; nutritional awareness through education; and modification of eating triggers (e.g., stress). Bariatric surgery may be considered as part of a comprehensive weight management programme in morbidly obese people with hip or knee OA (Fernandez et al., 2013*).

Figure 6 Weight loss in obese and overweight patients is advised for many health reasons, including improved outcome for osteoarthritis. There is evidence from randomised controlled trials that in the short term this improves function more than pain.

Patients with knee and hip OA should be advised about appropriate footwear. Shoes with thick but soft (e.g., air-filled) soles and no raised heels minimise rebound upward force transmission and adverse knee, hip and back alignment when walking (figure 7). This recommendation is primarily supported by expert opinion, but due to high levels of satisfaction and low cost, such shoes should be advised for all patients with knee and hip OA.

Figure 7 The worst shoe (left) for the health of feet, knees and hips, having a thin hard sole, narrow raised heel, narrow forefoot and shallow uppers. The better shoe on the right has a thick soft sole, no raised heel, a broad forefoot and a deep soft upper.

Review of the effectiveness of the use of lateral wedged insoles in patients with medial knee OA found no significant benefit on pain or function (Fernandes et al., 2013*). Historically, medial wedged insoles have been recommended for patients with lateral tibiofemoral OA or mild valgus malalignment. However, there is no clear evidence to support the use of one type of insole over another, and adverse effects including foot sole pain, low back pain and popliteal pain have been reported; as a result the recent EULAR non-pharmacological guidance document did not recommend the use of wedged insoles (Fernandes et al., 2013*).

Prefabricated foot orthoses and rocker-sole footwear can both improve foot pain in people with OA of the first metatarsophalangeal (MTP) joint, though insoles may be preferable as adherence and side effect profiles are better (Menz et al., 2016).

6 Simple analgesia and topical NSAIDs for pain control

The above core treatments can improve pain long term. However, in addition many patients benefit from the use of pharmacological agents for pain control.

6.1 Paracetamol (acetaminophen)

Paracetamol is an antipyretic analgesic with a central, although ill defined, mechanism of action. Paracetamol is relatively insoluble and is available in many different formulations, including dispersible for those who have difficulty swallowing tablets. The main potential for drug interactions is with warfarin. However, it does have some peripheral prostaglandin inhibition and although previously thought to not cause gastrointestinal (GI) or cardiovascular toxicity, there is growing evidence to associate paracetamol with many of the side effects recognised to occur with NSAIDs, especially GI bleeding (Zhang et al., 2010*; Hinz and Brune, 2012; Roberts et al., 2016). The combination of paracetamol and an NSAID particularly appears to increase the risk of GI events. Furthermore, paracetamol has to be used with caution as it has a narrow therapeutic to toxicity ratio, and at only several times its maximum recommended dose it can cause severe life-threatening hepatic failure, particularly in combination with alcohol intake. It should be mentioned that the tradition for the use of paracetamol in patients with OA differs significantly throughout European countries. The effect size for paracetamol in OA RCTs is only small and the main reason that it has been previously recommended so strongly as a first choice analgesic is because of its perceived safety (Jordan et al., 2003; Zhang et al., 2005*; Zhang et al., 2007a*; Zhang et al., 2007b*; Zhang et al., 2008*; NICE, 2008*), in addition to its low cost and ready availability. However, with the growing concerns over its safety and its recognised small effect size for chronic pain relief, paracetamol recommendations have recently changed. In 2014, OARSI declared its benefits ‘uncertain’ for patients with knee OA associated with comorbidity, although they have continued to recommend paracetamol for patients without comorbid conditions (McAlindon et al., 2014). They also recommend it is used with ‘conservative dosing and duration’. NICE (2014a*) has not changed its

pharmacological recommendations, pending an MHRA review of paracetamol safety, but it has drawn attention to the limited clinical effectiveness of paracetamol in the updated guidance.

6.2 Topical NSAIDs

Topical preparations are extremely popular with patients and associated with good adherence. It makes eminent sense to patients to apply a medicine directly to the painful site, and given that patients with OA usually only have only one or very few symptomatic joints at any one time, such an approach is feasible and well suited to OA. However, the benefits of topical NSAIDs are less clear for patients with multi-site OA.

Topical NSAIDs are strongly recommended for pain relief for hand OA and knee OA (figure 8) (Jordan et al., 2003; Zhang et al., 2007a*; NICE, 2008*; NICE, 2014a*). NICE recommend that topical NSAIDs should be considered as a first line drug option. When directly compared, topical NSAIDs have been shown to be as effective as the oral equivalent NSAID or coxib, but are associated with a lower incidence of GI and systemic side effects (equivalent to placebo) (NICE, 2008*). Topical NSAIDs produce <15% of the plasma levels of NSAID compared to oral administration, and one large case–control study has shown no increased risk of serious GI outcomes from topical NSAIDs (Evans et al., 1995). Topical NSAIDs vary greatly with respect to the active drug, carrier base and physical state (creams, gels, sprays), so they need to be considered as separate agents and the evidence for efficacy examined for each. This may explain the heterogeneity of systematic reviews that combine data from different agents. The two topical NSAIDs with the best research evidence for efficacy are diclofenac and ketoprofen. In general, there is moderate quality evidence of benefit, and very low quality evidence relating to harms; after 6 to 12 weeks, 6 out of 10 people with OA had much-reduced pain compared with 5 out of 10 for people treated with the topical placebo (the carrier agent) (Derry et al., 2016). Conaghan et al. (2013) have previously shown that the carrier agent can result in pain relief beyond that expected by an oral placebo, though the mechanism is not known.

Although reasonable synovial fluid levels of NSAIDs can be detected following their topical application, this largely relates to secondary blood-borne delivery rather than direct vertical penetration from the surface. However, in many patients with OA the origin of their pain may be periarticular rather than intracapsular, so this may not be crucial. Topical NSAIDs usually require application three times daily; they are smeared or sprayed onto the skin and do not need to be ‘rubbed in’ (this was a common misconception used to explain any efficacy observed).

Figure 8 Topical non-steroidal anti-inflammatory drug (NSAID) being used for thumb base osteoarthritis (OA) (left) and for knee OA (right).

Although reasonable synovial fluid levels of NSAIDs can be detected following their topical application, this largely relates to secondary blood-borne delivery rather than direct vertical penetration from the surface. However, in many patients with OA the origin of their pain may be periarticular rather than intracapsular, so this may not be crucial. Topical NSAIDs usually require application three times daily; they are smeared or sprayed onto the skin and do not need to be 'rubbed in' (this was a common misconception used to explain any efficacy observed).

7 Additional treatment options to consider for individual patients

A wide range of additional options are available. These are broadly divisible into pharmacological agents for pain control, biomechanical aids and appliances, and surgical interventions. They are listed here by group rather than in any order of priority.

7.1 Pharmacological agents

7.1.1 Topical capsaicin

This is a lipophilic alkaloid derived from chilli peppers. Capsaicin selectively binds to the protein TRPV1 (transient receptor potential vanilloid type 1), a heat-activated calcium channel on the surface of peripheral type C nociceptor fibres. When capsaicin binds to TRPV1, it lowers its threshold and activates the channel at lower than body temperature, giving a burning sensation. Prolonged activation of these neurons by repeated application of capsaicin gradually depletes presynaptic substance P, a key neurotransmitter for pain and heat, thus reducing the transmission of painful stimuli. Topical capsaicin applied four times daily can reduce pain associated with hand or knee OA (Jordan et al., 2003; Zhang et al., 2007a*; NICE, 2008*). It shows a

progressive effect that is usually maximal between 1 and 2 weeks. An initial burning sensation which wears off after the initial few days of application is very common, making it impossible to fully blind this agent in RCTs. It is available at concentrations of 0.025–0.075%. At the higher dose, over one third of patients are troubled by local burning, stinging or erythema and discontinue the treatment. It is therefore sensible to initially start at the lower dose. Patients should be warned to wash their hands carefully after application and to avoid contact with their eyes and mucosal membranes. The specific licensing arrangements for capsaicin vary between countries.

7.1.2 Oral NSAIDs (including selective COX-2 inhibitors)

Oral NSAIDs may be considered in patients who are unresponsive to acetaminophens. Numerically there are more RCTs of NSAIDs, including both non-selective and selective COX-2 inhibitors (coxibs), than all other OA treatments combined, producing a skewed research evidence base towards this one modality (figure 9).

Figure 9 The epidemiology of clinical trials in knee osteoarthritis showing a large bias towards randomised controlled trials of oral non-steroidal anti-inflammatory drugs (NSAIDs). IA HA, intra-articular hyaluronan; NSAIDs, non-steroidal anti-inflammatory drugs; SYSADOA, symptomatic slow acting drugs for osteoarthritis. (Reproduced from Pendleton et al., *Ann Rheum Dis* 2000;59:936–44.)

There is clear RCT evidence for efficacy of oral NSAIDs above placebo, and data to show superior efficacy of NSAIDs compared to paracetamol, but no consistent data supporting superior efficacy of one NSAID or chemical class over another (on the contrary, most RCTs show equivalence between NSAIDs and coxibs in OA

at different sites). In general terms, however, NSAIDs are not very potent analgesics for OA. As with many other analgesics, discontinuation rates for oral NSAIDs are high (40–50% at 2 months, over 80% by 12 months), and substitution studies have shown ease of withdrawal of chronic NSAIDs from patients with OA, in place of simple analgesia and lifestyle advice, without any worsening of OA symptoms.

The main concern with NSAIDs, of course, is life-threatening toxicity. NSAIDs can cause serious GI complications such as peptic ulcers, perforations and obstructions as well as bleeds. This risk increases especially with age and concurrent use of other medications, such as warfarin, platelet aggregation inhibitors or SSRIs (selective serotonin reuptake inhibitors). Current European recommendations for prescribing NSAIDs in patients at increased risk of GI toxicity are to use a COX-2 selective agent or a non-selective NSAID plus a proton pump inhibitor (PPI) or misoprostol for gastro-protection. Unfortunately, the reduced GI risk associated with the use of COX-2 selective agents is largely lost when low-dose aspirin is co-administered. It is important to note that non-selective NSAIDs cannot substitute for low-dose aspirin treatment for cardiovascular indications, as aspirin is the only irreversible inhibitor of COX-1.

As a group, patients with OA are predominantly in the category of increased GI risk through being over 65 years of age and/or having comorbidity, including cardiovascular disease, justifying prophylaxis with gastro protection. Because of this, and for cost effectiveness reasons, NICE (2008*) guidelines recommend co-prescription of a PPI with both non-selective and COX-2 selective agents for any patient with OA. Such an approach additionally reduces the incidence of less serious but troublesome dyspepsia that can occur with both NSAIDs and COX-2 selective inhibitors. For any NSAID, the lowest dose should be given first and only increased if there is insufficient benefit. In any case, NSAIDs should be administered at the lowest effective dose for the shortest time necessary.

In addition to GI toxicity, there is considerable concern over cardio-renal safety. There is growing evidence that this risk is common to both unselective NSAIDs and COX-2 selective agents, although the degree of risk may vary between individual drugs. For example, the estimated increase in risk of serious cardiovascular events (mainly myocardial infarction or stroke) with ibuprofen (relative risk (RR) 1.51, 95% CI 0.96,2.37) is similar to diclofenac (RR 1.63, 95% CI 1.12,2.37), but the risk may be lower from naproxen (RR 0.92, 95% CI 0.67,1.26). The current advice from the European Agency for the Evaluation of Medicinal Products (EMA) is that COX-2 selective NSAIDs are contraindicated in patients with ischaemic heart disease or stroke and that prescribers should exercise caution when prescribing COX-2 inhibitors for patients with risk factors for heart disease, such as hypertension, hyperlipidaemia, diabetes and smoking, as well as for patients with peripheral arterial disease. This again includes a high proportion of older patients with OA. Direct renal toxicity, especially in the elderly, and multiple drug interactions (especially with diuretics and antihypertensive medication) are further major safety concerns in the OA population. Therefore, this group of drugs is commonly contraindicated in the

majority of patients with OA, and increasingly as they age. A further, though less well studied, concern is possible musculoskeletal safety. For example:

- There are animal data that suggest that NSAIDs can inhibit bone repair and may have adverse effects on cartilage metabolism, especially OA cartilage.
- One RCT has suggested that an oral NSAID (indomethacin) may cause more rapid joint space loss in patients with knee OA (that is, it is a negative disease-modifying agent) (Huskisson et al., 1995).
- Several NSAIDs given at normal doses following hip replacement surgery can prevent heterotopic new bone formation (figure 10), raising concerns over possible effects on bone remodelling and osteophytosis in OA.

Figure 10 Heterotopic new bone formation followed this patient's right total hip replacement, causing pronounced hip restriction. This complication was prevented when the patient underwent subsequent left hip replacement followed by 6 weeks of postoperative oral non-steroidal anti-inflammatory drug treatment.

7.1.3 Opioids

Although opioids are widely recommended and used, there are very few RCTs (all short-term) in patients with knee, hip or hand OA, and little data to suggest that dose escalation is effective (Jordan et al., 2003; Zhang et al., 2005*; Zhang et al., 2007a*; Zhang et al., 2007b*; Zhang et al., 2008*; Zhang et al., 2010*; NICE, 2008*). Side effects largely limit their use and are more common in the elderly, the most troublesome being nausea, constipation, dizziness, confusion, somnolence and itching, with a number needed to harm (NNH) of 5. Dependence and possible addiction from long-term use for non-cancer pain are further limiting factors. Nevertheless, the use of opioids increased dramatically in the USA and some other countries following the withdrawal of rofecoxib and the growing concerns about the safety of NSAIDs. Most guidelines recommend

that if paracetamol and topical agents are ineffective, then the addition of ‘weak’ opioids (e.g., codeine, dihydrocodeine, tramadol) should be considered. Stronger opioids (e.g., oxymorphone, oxycodone, fentanyl, morphine sulfate) should only be used for severe OA pain in exceptional circumstances, predominantly as a short-term interim measure before surgical intervention.

7.1.4 Amitriptyline and antidepressants

Duloxetine, a serotonin-norepinephrine reuptake inhibitor, has been recommended by OARSI for patients with knee OA and patients with multisite OA, following RCT evidence demonstrating that it has beneficial effects on pain (McAlindon et al., 2014*). Side effects include nausea, dry mouth, somnolence and fatigue among others, but it is usually reasonably well tolerated. OARSI have given it an ‘uncertain’ recommendation for patients with knee only OA and comorbidities due to the availability of other more targeted therapies and its side effect profile.

There are scant data (mainly for imipramine) to support the use of low-dose tricyclic antidepressants as analgesics in OA. However, low-dose amitriptyline may be considered for refractory pain in patients with OA who also have non-restorative sleep (as amitriptyline can improve delta sleep). Depression is a common comorbidity, and in patients with OA and depression, successful treatment of their depression can improve pain and disability associated with OA, reinforcing the requirement and success of holistic assessment and management in OA (Fernandes et al., 2013*).

7.1.5 Nutraceuticals

‘Nutraceuticals’ is a term used to cover a wide range of natural products and foods that are thought to have health benefits. For OA there are numerous nutraceuticals that claim either pain relieving benefits and/or retardation of joint damage that are available for self-purchase in pharmacies, health food stores and supermarkets, and these are sometimes referred to as SYSDOA (symptomatic slow-acting drugs for OA). Being food products there are no strict regulations concerning the validity of such claims and no compulsory quality control. Nevertheless, such products are extremely popular and have huge sales worldwide. The rationale for the use of glucosamine and chondroitin is that they are basic components of cartilage glycosaminoglycans and that dietary supplementation will improve the integrity of the hyaline cartilage matrix. There is no clear rationale, however, for any mechanism of pain relief in OA.

The mode of action and both in vitro and in vivo effects of these compounds remain highly controversial, although their safety is rarely disputed. Overall, the RCT evidence for slow onset symptom benefit is best for glucosamine sulfate at a single dose of 1500mg/day. A network meta-analysis found no benefit from glucosamine salts (Wandel et al., 2010).

There is meta-analytical evidence from mainly low-quality studies that chondroitin sulfate can give small-to-moderate pain relief effects in OA (Singh et al., 2015). There is low-to-moderate evidence that diacerin has minimal effects on pain and only a small benefit on joint space narrowing (Fidelix et al., 2014.). It has been associated with a high rate of adverse events such as diarrhoea, with restrictions placed on its prescription in Europe. A systematic review and meta-analysis comparing Avocado Soybean Unsaponifiables (ASU) with placebo in patients with knee and hip OA demonstrated a small benefit for pain in favour of ASU (Christensen et al., 2008).

Data on these products is heterogeneous, possibly prone to publication bias, and most guidelines do not support the use of nutraceuticals for pain reduction in OA. NICE, considering cost-effectiveness, have recommended not to use nutraceuticals.

7.1.6 Intra-articular glucocorticoid

There is RCT evidence to justify IA injection of long-acting glucocorticoid for pain relief in knee and hip OA (figure 11). This intervention is quick and simple to do and has a large effect size (ES 1.27 at 7 days post-injection for pain relief against placebo for knee OA). It produces relatively rapid relief of severe pain within a few hours to a few days. This benefit is relatively short lasting in RCTs; in knee OA, small to moderate effects on pain relief are seen at 4-6 weeks post injection with small effects seen at 13 weeks and similarly in hip OA, pain relief has been demonstrated 8 weeks post injection. However, individual patients may derive benefit for longer. In knee OA, there are no clear clinical predictors of response such as presence of effusion, synovitis or degree of structural damage. However, some studies in hip OA suggest that low body mass index (BMI), radiographic severity and synovitis may be predictors of outcome (Hirsch et al., 2013).

Figure 11 Intra-articular injection of glucocorticoid is helpful for quick control of pronounced pain from thumb base OA (left), knee osteoarthritis (OA) (right), and other joints.

There is less trial evidence for OA at other sites, but this treatment is recommended in all guidelines, being well supported by expert opinion. Other joints affected by OA that are commonly injected include the trapeziometacarpal, acromioclavicular and first metatarsophalangeal joint.

Although sepsis is a theoretical concern, as long as sensible sterile precautions are observed, IA steroid injection is a very safe, easily undertaken and well tolerated procedure (Courtney and Doherty, 2005). The main side effects encountered in practice in a minority of patients are:

- temporary pain exacerbation or post-injection 'flare' (this can follow any joint aspiration or injection, even when saline is injected)
- post-injection facial flushing, which is mostly limited to women and may last for 24–72 h post-injection; this is a constitutional reaction that is likely to recur with subsequent injections
- worsening of blood and urine sugar values in diabetic patients for 24–48h, occasionally requiring adjustment of diabetic treatment.

IA steroid injection is a very useful treatment to instil confidence and optimism in a patient. It helps them realise that their pain can be helped and may encourage a more positive approach to other elements of their management plan. It is particularly helpful at providing a temporary respite to allow the patient to commence physical interventions such as neuromuscular training, or to tide the patient over an important event such as a family wedding or holiday.

7.1.7 IA hyaluronan

Hyaluronic acid (HA), also known as hyaluronan or hyaluronate, is a large molecular weight glycosaminoglycan that is a constituent of many tissues including both the synovial and cartilage extracellular matrix. The viscoelastic properties of HA aid joint lubrication and maintain tissue hydration, but HA also has many other biological actions including interaction with other extracellular macromolecules and cell receptors, including CD44. HA is the major non-protein component of synovial fluid and it is cleared from the joint via the lymphatic circulation and degraded by hepatic endothelial cells. Synovial lining cells are the main source of articular HA, and serum HA measurements have been investigated as a biomarker of synovial reactivity. The initial rationale to use HA in OA was to correct the reduced HA molecular weight and concentration observed in OA synovial fluid and to improve joint lubrication—so-called 'viscosupplementation' (figure 12). A range of HA preparations is now available, varying in terms of molecular weight, degrees of cross linkage and polymerisation, and source of manufacture.

There are RCTs in knee OA to support pain relief from various HA preparations that is superior to placebo at 3 months post-injection, but improvements are small (pooled ES 0.21, 95% CI 0.10,0.32) (Richette et al., 2015). RCTs in hip OA have shown similar results.

Figure 12 In osteoarthritis there is reduction in hyaluronic acid (HA) concentration, molecular weight and polymerisation, leading to reduced viscosity of synovial fluid. The rationale of 'viscosupplementation' by injection of HA was to correct these physicochemical abnormalities to aid joint lubrication.

Most preparations require a course of three to five weekly injections to demonstrate symptom benefit, which poses logistical and cost disadvantages. A single injection preparation is available but has limited clinical trial data at present. Post-injection flares are infrequent but can be more florid than those seen with steroid or saline injections. Most guidelines, with the exception of NICE (2008*), give guarded recommendation for consideration of HA in OA.

7.2 Biomechanical aids and appliances

7.2.1 Sticks and walking aids

Walking aids (figure 13) can reduce pain in patients with hip and knee OA, and reduction of impact loading theoretically might reduce the rate of structural progression of OA.

Patients should be given formal instruction in the optimal use of a cane or crutch in the contralateral hand (Jones et al., 2012). Frames or wheeled walkers are often preferable for those with bilateral disease and are particularly helpful for certain tasks requiring walking and carrying—for example, when out shopping. There is a sound biomechanical rationale for the use of a walking stick and observational evidence that use of a stick in the contralateral hand reduces the adduction moment across the medial tibiofemoral compartment and mechanical loading through the hip. The magnitude of the adduction moment has been demonstrated as a risk

factor for structural progression of knee OA, so it is feasible that use of a stick could have more than immediate benefits on pain reduction. Use of a stick or walking aid is recommended in all guidelines for knee and hip OA (Jordan et al., 2003; Zhang et al., 2005*; Zhang et al., 2007b*; Zhang et al., 2008; Zhang et al., 2010*; NICE, 2008*; NICE, 2014a*; Fernandes et al., 2013*). Non-use is often associated with negative perspectives of walking aids so, as always, a detailed discussion with the patient and a clear explanation of benefits is required.

Figure 13 (A) There is a wide range of walking sticks and walking aids to suit the individual. These can all reduce mechanical loading across a knee or hip that is compromised by osteoarthritis. (B) Nordic walking poles.

7.2.2 Braces, splints and other biomechanical approaches

In patients with knee OA and mild to moderate varus or valgus instability or malalignment, a knee brace can reduce pain, improve stability and diminish the risk of falling. A Cochrane review (Duivenvoorden et al., 2015) indicates that the evidence base is inconclusive (low-quality evidence suggests a lack of benefit) for the effects of knee braces on pain, function, and quality of life for people with OA of the medial compartment of the knee.

For patients with severe symptomatic thumb base OA, splints are recommended for pain relief and to correct lateral angulation and flexion deformity. Two small RCTs comparing the effects of a full splint (covering both thumb base and wrist) versus a half splint (only protecting the thumb base) in patients with first carpometacarpal OA have shown that inclusion of a wrist component gives better pain relief (ES 0.64, 95% CI 0.02, 1.96; number needed to treat (NNT) of 4 for improvement of patient daily life activity). As part of core

management, patients should be advised on pacing of hand usage, and to avoid repetitive power grip, pinch and twisting movements.

For patients with pronounced symptoms and functional difficulties from hand, hip or knee OA, adjunctive assistive devices may be required to modify the patient's environment in a way that reduces mechanical loading and facilitates specific actions. Examples for hand OA include enlarged grips on pens or cutlery, non-slip mats to assist opening objects, and electric can-openers in the kitchen (Zhang et al., 2007a*; Fernandes et al., 2013*). International guidelines recommend the use of joint protection as an effective intervention for medium-term outcome in hand OA. In the first large-scale randomised trial to investigate the clinical effectiveness of two self-management programmes for community-dwelling adults aged 50 years and over with hand OA (Dziedzic et al., 2015), occupational therapists delivered an intervention targeting the following joint protection principles:

- distributing the weight of what you lift over several joints (e.g., spread the load over two hands)
- avoiding putting strain on the thumb and repetitive thumb movements
- avoiding prolonged grips in one position
- using as large a grip as possible
- reducing the effort needed to do a task (e.g., use labour-saving gadgets, avoid lifting heavy objects, and reduce the weight of what you lift)
- energy conservation (activity pacing and planning).

At 6 months, 33% assigned joint protection were responders compared with 21% with no joint protection ($p=0.03$). While differences in most secondary outcomes for joint protection were not statistically significant, improvement in pain self-efficacy was noted at each step (3-month $p=0.002$; 6-month $p=0.001$; 12-month $p=0.03$).

For knee or hip OA, replacing a bath with a walk-in shower or using raised toilet seats and chairs may be beneficial (Fernandes et al., 2013*). For patients with problems undertaking activities of daily living, it may be helpful to seek expert advice from occupational therapists or from disability equipment assessment centres.

7.3 Other non-pharmacological treatments

7.3.1 Acupuncture

Acupuncture is an ancient treatment with multiple potential mechanisms of action including release of endogenous opioid. It is practised by many allied health professionals, but although there is an extensive

research base examining the efficacy of acupuncture, interpretation is difficult because of variability both in delivery and in controls. A typical treatment involves six or more needles inserted near the painful joint and sometimes at more distant sites, which may then be manipulated to produce a 'needle sensation', stimulated electrically (electroacupuncture) or warmed by burning a dried herb (moxa) on the needle end. A course of treatment usually involves six or more such sessions. In RCTs clearly it is impossible to blind the practitioner and difficult to blind the patient, but placebo 'sham acupuncture' has been attempted by inserting needles into the wrong place and not stimulating them or by using blunt retractable needles that cause pressure but not skin penetration. However, there is concern over whether such sham controls are a completely inactive placebo. Unsurprisingly, there is heterogeneity of results from RCTs. Some meta-analyses do report pain relief from acupuncture compared to placebo, however the effect size is small and any benefit appears relatively short, lasting from 2 to 6 weeks, and in the recent update of NICE recommendations (2014a) acupuncture was not recommended for use.

7.3.2 Thermotherapy

Thermotherapy is locally applied heat or cold. There is little research evidence but it is used widely by patients with OA. Heat can be applied in various ways such as by application of heat packs, by immersion in warm water or wax baths or by diathermy, while local cold is usually administered by ice packs or by massage with ice. Heat and cold are recommended in most guidelines as a simple and safe adjunct to the self-management of pain (Fernandes et al., 2013*; NICE, 2014a*).

Balneotherapy is a popular modality in some European healthcare systems (defined as the use of baths containing thermal mineral waters) and includes practices such as Dead Sea salt or mineral baths, sulphur baths and radon-carbon dioxide baths (McAlindon et al., 2014*). In the OARSI guidelines for the non-surgical management of knee OA, balneotherapy was considered appropriate only for the sub-phenotype with multiple-joint OA and comorbidities, due to paucity of treatment alternatives for that group (McAlindon et al., 2014*).

7.3.3 Transcutaneous electrical nerve stimulation

Transcutaneous electrical nerve stimulation (TENS) may give safe and effective pain relief in some patients with OA (NNT 3; 95% CI 1,5), and is recommended as a safe adjunctive modality in the majority of guidelines. TENS produces pulsed currents via electrodes placed on the skin; the rationale for its use is selective electrical stimulation of peripheral sensory fibres that then cause inhibition of nociceptive nerve transmission via gating at a segmental cord level (figure 14). If used, patients should receive training and written instruction with respect to selection of stimulation intensity and appropriate placement of electrodes, and be reassessed after an initial trial period. Patients should be encouraged to experiment with different intensities and duration of application if the desired relief is not achieved initially, allowing control of symptoms as part of self-

management. In one RCT, even a single TENS treatment increased the pressure pain threshold in people with knee OA. On the other hand, subjective pain ratings at rest and during movement were similarly reduced by active TENS, suggesting a strong placebo component to the effect of TENS (Fernandes et al., 2013*; NICE, 2014a*).

Figure 14 One of many commercially available compact and portable transcutaneous electrical nerve stimulation devices. (Source: Five Star medical Supply, <http://www.fivestarmedicalsupply.com>)

7.3.4 Therapeutic ultrasound

A double blind, randomised, placebo controlled pilot study to determine the feasibility of conducting an RCT assessing the effect of low intensity pulsed ultrasound therapy on cartilage repair in participants with mild to moderate knee OA, showed an increase in medial tibial cartilage thickness in the active ultrasound therapy group. On the other hand, a randomised double blind controlled clinical study showed that therapeutic ultrasound has no further significant effect on symptoms in people with knee OA, so evidence remains equivocal. Previously, European recommendations for the management of hand OA recommended ultrasound in combination with warmth, but this was based mainly on consensus opinion (Zhang et al., 2007a*).

7.3.5 Behavioural interventions

Cognitive behavioural therapy can improve sleep for people with OA but there is no evidence that this has a beneficial effect on pain itself or on pain coping (Smith et al., 2015). An internet-delivered combination of exercise advice and training plus pain coping strategy training (PainCOACH) was found to improve pain and function for at least six months (Bennell et al., 2017).

7.4 Surgery

For patients with severe hip or knee OA, total hip arthroplasty (THA) and total knee arthroplasty (TKA) are widely recognised as reliable and appropriate surgical procedures to control pain, restore function and improve quality of life (figure 15). Evidence for their efficacy is based on numerous uncontrolled observational studies and several large cohort studies as well as a wealth of expert and patient opinion. Successful outcomes require: careful selection of patients most likely to benefit; thorough preparation in terms of optimising general health and patient information; well performed anaesthesia and surgery; and appropriate rehabilitation and domestic support for the first few postoperative weeks. Skou et al. (2015) found that, in patients eligible for knee replacement who were randomised to total knee replacement plus 12 weeks of subsequent nonpharmacological management (exercise, education, dietary advice, insoles, analgesia) or the 12 weeks' nonpharmacological management only, there was a greater improvement in pain and function in the surgical group (adjusted mean difference of 15,8 points in the KOOS score, favouring surgery) but most patients in the nonsurgical group did not undergo subsequent arthroplasty within the 12-month follow-up period; the surgical group had a higher incidence of serious adverse events (48% vs. 12%). An abstract reporting the two-year follow-up (Skou et al., 2017) identified that nearly two-thirds of patients eligible for surgery but randomised to nonsurgical treatment postponed surgery for at least two years after randomisation. Continued use of a nonsurgical approach may therefore be a reasonable strategy, coupled with appropriate ongoing clinical review.

Recovery from TKA is slower than from THA, but with appropriate rehabilitation from the first postoperative day most patients resume normal activities within 6–12 weeks. All studies show substantial improvements in pain and function, although generally THA is more effective than TKA in restoring function to normal; quality of life indices 1 year after THA have been shown to be comparable to age and gender matched non-OA controls. Over 95% of joint replacements continue to function well into the second decade after surgery, and most provide lifelong pain-free function. However, approximately one in five patients is not satisfied with their replacement and a minority gets little or no improvement in pain following joint replacement.

All guidelines agree that referral for consideration of THA or TKA should be considered in patients with hip or knee OA who experience persistent pain, stiffness and reduced function that are refractory to non-surgical treatments and which impact significantly on their quality of life (Jordan et al., 2003; Zhang et al., 2005*; Zhang et al., 2007b*; Zhang et al., 2008*; Zhang et al., 2010*; NICE, 2008*; NICE, 2014a*). Joint replacement is very effective at relieving these symptoms and carries relatively low risk both in terms of systemic complications and suboptimal outcomes for the joint itself. Importantly, referral should be made after core treatments have been tried, but before there is prolonged and established functional limitation and severe pain, since this may compromise a good outcome following surgery. Orthopaedic scores and questionnaire-based assessments are available to assess pain, functional impairment and X-ray damage (e.g., the New

Zealand score and the Oxford hip or knee score), but these have not been validated to assess appropriateness of referral. As there is no common consensus on when joint replacement should be carried out, a shared decision, between doctor and patient, on when surgery should be performed should be based on an individualised risk/benefit estimation.

Figure 15 A total hip arthroplasty. Joint replacement involves removal of the articular surfaces and replacement with synthetic materials, usually metal and plastic (sometimes ceramic), with or without use of bone cement to stabilise the implanted components.

The decision to refer for surgery is individual and ultimately it is the patient who must decide based on their own risk/benefit calculation depending on their symptom severity, their general health, their expectations of lifestyle and activity, and the effectiveness of the non-surgical treatments they have tried. Patient-specific factors such as age, gender, smoking, and presence of obesity or other comorbidity should not be barriers to referral for joint replacement. Some patients will have higher risks of postoperative complication or higher risk of long-term prosthesis failure, but there is no evidence to support these as reasons to deny treatment. Specifically, there is no evidence to support poorer outcomes from THA or TKA in patients who are obese, have multiple comorbidities or are of advanced age, and these factors should not be barriers to referral (NICE, 2014a*). On the contrary, there is evidence that these patients can have greater benefit than other groups.

Patients with involvement of just one tibiofemoral compartment may be considered for unicompartmental knee arthroplasty (figure 16) (NICE, 2008*; Zhang et al., 2008*). If this lesser procedure fails, it does not preclude subsequent consideration of a TKA. Tibial osteotomy for medial compartment knee OA has also been identified to be beneficial in a Cochrane review (Brouwer et al., 2014), though it is not known how this compares to nonsurgical treatment or to a unicompartmental arthroplasty.

Figure 16 A unicompartmental joint replacement for medial tibiofemoral osteoarthritis.

Because the risk of subsequent implant failure, predominantly from loosening, is greater in younger, more mobile patients and in those who practise sports, corrective osteotomies and joint preserving procedures (e.g., hip resurfacing) may be considered in such patients.

Due to lack of evidence to support arthroscopic lavage and debridement for knee OA, these invasive procedures should not be offered as part of treatment for OA itself, but should be considered in a patient with knee OA if, in addition to their OA symptoms, there is a clear history of mechanical locking, but not just for stiffness, ‘giving way’ or X-ray evidence of osteochondral ‘loose’ bodies (NICE, 2008*). In a systematic review, arthroscopic surgery for knee OA has been found to have an “inconsequential” benefit that is short-lived, disappearing within one to two years (Thorlund et al., 2015).

Surgery should also be considered at other joint sites for severe symptomatic OA refractory to other measures. The specific surgical options will vary according to each joint. For example, several procedures are available for thumb base OA including arthrodesis, trapeziectomy alone or with synthetic or biological interpositions, osteotomy and total joint replacement. Two systematic reviews suggest that there are no benefits but more

complications from combined procedures, so simple trapeziectomy is generally recommended (figure 17) (Zhang et al., 2007a*).

Figure 17 *Trapeziectomy for first carpometacarpal joint osteoarthritis, in this patient resulting in a successful outcome in terms of pain relief and functional improvement.*

7.5 Disease-modifying OA drugs

Although there is considerable interest in the possibility of drugs that may beneficially modify the biochemical and structural changes of OA, currently no guidelines recommend any drug for this purpose. RCTs to investigate slowing of radiographic cartilage loss in patients with knee OA have been undertaken with glucosamine, chondroitin, diacerein, doxycycline, risedronate, strontium and hyaluronan. Two placebo controlled RCTs of glucosamine sulfate 1500 mg/day have reported a reduction in radiographic medial tibiofemoral joint space loss at 3 years with a pooled ES of 0.24 (95% CI 0.04,0.43); and a meta-analysis of five placebo controlled RCTs of chondroitin sulfate 800 mg/day has reported a small difference of 0.16 mm (95% CI 0.08,0.24 mm) in medial compartment minimum joint space after 2 years. A single RCT of diacerein in patients with primary hip OA has demonstrated slowing of joint space loss after 3 years, but no effects were observed in a 1-year study of diacerein for knee OA. A single study of doxycycline, in obese women with knee OA, demonstrated less reduction in medial joint space after 30 months in the index knee of patients on doxycycline (0.30 ± 0.6 mm vs 0.45 ± 0.70 mm), but paradoxically no effects on the contralateral knee. Evidence from two relatively short-term studies of hyaluronan and risedronate in knee OA are inconclusive. Reginster et al. (2013) investigated the use of strontium in knee OA and identified that both 1g and 2g daily doses were associated with less joint space loss than placebo (0.23mm for the 1g/day dose, 0.27mm for the 2g/day dose, compared to 0.37mm for placebo); pain and function were also better in the 2g/day dose group. Strontium treatment for osteoporosis has previously been the subject of a safety warning (<https://www.gov.uk/drug-safety-update/strontium-ranelate-cardiovascular-risk>). Vitamin D has recently been investigated for its role in

improving the health of cartilage, bone and muscle in OA but found not to improve knee pain nor cartilage volume loss (McAlindon et al., 2013).

There are a number of caveats and issues with such studies, including the small effect sizes and the lack of clear evidence for any significant improvement in patient centred outcomes (pain, function, quality of life) for any apparent slowing of cartilage loss. Such therapies predominantly target one joint tissue, specifically cartilage (glucosamine, chondroitin, doxycycline, diacerein) or bone (risedronate), and because all joint tissues are involved in OA, it may be unrealistic to expect overall improvements by influencing just one of the component tissues.

7.6 Possible new therapeutic options

Two disease-modifying anti-rheumatic drugs (DMARDs) used in the treatment of inflammatory arthritis are currently being investigated for their role in OA. Hydroxychloroquine has been evaluated in two small RCTs in knee and hand OA, with improvements in symptoms and function reported (Kingsbury et al., 2013). An abstract (Kingsbury et al., 2017) of results from the UK HERO trial evaluating hydroxychloroquine identified no benefit over placebo. Methotrexate has also been the subject of one RCT in knee OA, but the associated publication was withdrawn in 2016. Methotrexate is currently being evaluated in larger multi-centre RCTs in hand OA and knee OA, respectively.

Targeting nerve growth factor as a therapeutic option showed promise when the monoclonal antibody, tanezumab, demonstrated marked analgesic efficacy in OA of the knee; however, development of this drug is still on hold after increased rates of joint replacement were reported in the treated arm of this phase II trial.

IL-1, a main inflammatory cytokine in the pathophysiology of OA, represents one of the possible treatment targets. Although pre-clinical studies have suggested benefit from IL-1 blockade on activity and progression of OA, clinical studies have thus far failed to demonstrate similar results in humans with systemic or intra-articular drugs (Chevalier et al., 2011). TNF α blockade (administered systemically and intra-articularly) has also been evaluated in three small RCTs in hand and knee OA; these studies did not demonstrate any impact on clinical outcomes, although reduction in radiographic erosion rate was reported in swollen proximal interphalangeal joints (PIPs) in a study of hand OA (Verbruggen et al., 2012). Other agents under current investigation include nitrous oxide, protease inhibitors and inflammatory cytokine intracellular signalling cascades (Pulsatelli et al., 2013).

The injection of autologous platelet-rich plasma has some limited data on effectiveness in reducing pain and improving mobility in knee OA; in theory, cartilage repair may be enhanced by injection of the patient's own blood products. Although RCTs have demonstrated some improvement in clinical outcomes, none have demonstrated visual evidence, arthroscopically, of cartilage repair. NICE have reviewed this intervention and

concluded there is insufficient evidence to recommend this treatment; however, the procedure is considered safe and may be conducted under special arrangements for clinical governance, consent and audit or research (NICE, 2014b).

A food supplement or nutraceutical that has some limited clinical data to support short-term symptom relief is an extract from *Scutellaria baicalensis* and *Acacia catechu* (otherwise known as UP446), thought to be a leukotriene and prostaglandin inhibitor (Sampalis and Brownell, 2012).

Finally, studies of intra-articular cellular therapy injections for osteoarthritis and focal cartilage defects in the human knee have suggested positive results with respect to clinical improvement and safety. However, the improvement was modest, a placebo effect cannot be disregarded and the methodological quality of the literature was poor (Chahla et al., 2016).

8 Caveats to the research base for OA management

RCTs can play an important role in showing whether an individual treatment can be effective in a carefully controlled setting—that is, whether a treatment has clinical efficacy. However, many RCTs have limitations and caveats that reduce the generalisability of the trial findings to the varied population of people with OA encountered in everyday clinical practice. It is therefore common for the more important clinical effectiveness of the treatment outside of a trial setting to be less impressive than the effect size demonstrated in an RCT. The most common limitation to any RCT is bias, and the most common form of bias is selection bias. Although a large number of RCTs have investigated the efficacy of a range of treatments in OA, there are important limitations to the research base in OA. For example:

- The majority of OA trials focus on knee OA and there are relatively few RCTs for other joints targeted by OA. However, OA at sites such as the knee, hand and hip differs in terms of prevalence and incidence, the profile of risk factors for development and progression, and prognosis for clinical outcome. In addition, there are limited data to suggest that the same treatment, such as an oral NSAID, may have a bigger effect size at the knee than at the hip, and that even the placebo effect in OA may vary between sites, being greatest at the hand, lower at the knee, and least at the hip. Therefore, RCT results gained at one site cannot necessarily be extrapolated to another site of OA—each requiring study in their own right.
- A common selection bias in most RCTs is that patients with OA are recruited from secondary care, yet the majority of patients with OA are managed solely in primary care.
- The majority of RCTs are relatively short term, from a few weeks to a few months, and very few last 1–2 years or more. This results in a paucity of data regarding long-term benefits of treatments in OA and possible emergence of long-term side effects.

- The majority of trials in OA are of drug treatments, giving undue emphasis to pharmacological agents in the research base.
- Many RCTs of drug treatments for pain require patients to 'flare' (that is, show a certain degree of worsening of symptoms) on stopping their current medications before entering a study. Such flare designs have a bias towards patients who respond to medication, and thus tend to inflate the treatment response.
- Most studies investigate the efficacy of a single intervention even though multiple treatments are given in practice. Very few studies examine the benefits of two or more combined treatments and whether there is interaction, above simple addition, between treatments. Factorial designs that randomise patients to either (1) treatment A, (2) treatment B, (3) treatment A + B, or (4) placebo, are uncommonly used for OA trials yet give clinically informative results.
- Patients with OA recruited for RCTs are usually subject to a large number of exclusions, such as being elderly, having comorbidity, being on certain medications, having a knee effusion or having severe radiographic change. This tends to make the study sample homogeneous and medically robust. This has advantages in terms of reducing the numbers needed for the trial, reducing the likelihood of side effects and minimising costs, but such a sample may not be representative of patients with OA in general (figure 18). Results of such studies often have poor generalisability and lack information concerning clinical predictors of response—for example, do certain patients with pronounced X-ray change, a knee effusion or gross obesity do less well than those without such features? A better study design would be to reduce exclusion criteria, including people with comorbidities. This heterogeneity is more representative of the whole population with OA, but has the disadvantages of requiring more patients to be randomised and of increasing costs. However, results of such studies have good generalisability and can answer what most practitioners want to know: which patient is likely to do best with this particular treatment?

Such multiple caveats reduce the usefulness of many trials in terms of guiding clinical decision making. However, the quality, both of design and of reporting of RCTs, continues to improve and is aided by publication conventions such as CONSORT which require inclusion of key elements such as a flow diagram showing the number of participants at each stage of the study (from those eligible to those that complete), the method of recruitment and the exact randomisation procedure, using a check list to ensure full inclusion of essential information. Nevertheless, it is important to examine each study critically, especially in terms of the common intrinsic biases listed above, and to judge the possible relevance of the trial results to your own patient population with OA.

Figure 18 Randomised controlled trials in osteoarthritis usually study a small sample of homogeneous patients (dark blue), subject to the same exclusions, from the whole population of osteoarthritis (left). Studies with little exclusion require more participants (heterogeneity requires greater numbers for randomisation to distribute variation equally) (multi-coloured) but produce more generalisable data and, because of variation between participants, can examine predictors of response to the treatment.

9 Quality of care in OA

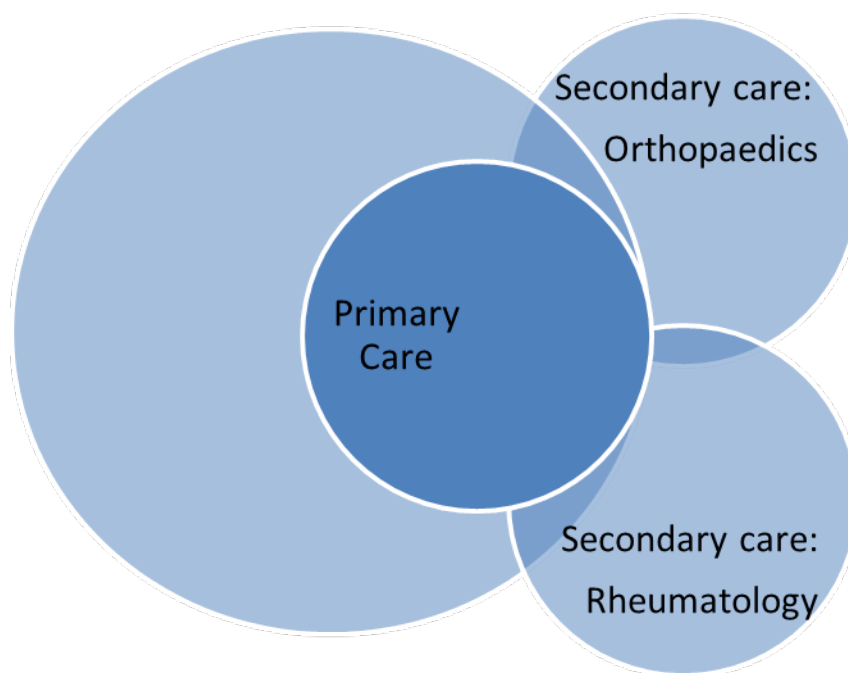

Despite the existence of concordant evidence-based guidelines for the management of OA, whenever the care of patients with OA has been audited in recent years, it is apparent that the standard of care is often suboptimal. In the community, the core elements (education, exercise prescription, reduction of adverse mechanical factors) are often omitted and the most common treatment approach hinges around drug treatments, predominantly NSAIDs.

Routine audit of and feedback on clinical care for OA is needed to improve the quality of that care and has prompted an interest in measures of quality of OA care. Such indicators are defined as a 'measurable [element] of practice performance for which there is evidence or consensus that it can be used to assess the quality, and hence change in the quality, of care provided' (Lawrence and Olesen, 1997). A systematic review identified that there are a number of well-validated indicators that could be used to capture processes of care for primary care (Edwards et al., 2013). Edwards et al. (2014) tested quality indicators in an electronic pop-up template in primary care consultations and demonstrated that use of computer prompts helps to improve the uptake of first line analgesia with an increase in use of topical NSAIDs with template use. The EUMUSC.net project (<http://www.eumusc.net/>) is a European initiative to develop standards of care and has also suggested a set of indicators for OA. Østerås et al. (2013) have generated a patient self-report measure of quality indicators which has been replicated by primary care researchers in the UK (Dziedzic et al., 2014).

10 Models of care

OA is one of the most common long-term conditions and as such needs to be centrally managed in primary care. Indeed, the care of patients with OA starts even before they consult a healthcare practitioner and the ARMA standards of care for OA highlight the importance of community services in health promotion and supporting self-management (figure 19). Joint problems are the most common cause of restriction in daily life in most countries and healthcare for such problems is frequently provided in primary care settings.

Figure 19 The care of patients with osteoarthritis.

10.1 OA in primary care: the role of the multidisciplinary team

Although the biomedical model has contributed to major advances, a model that embraces chronic pain management and its psychological and social components is needed. Primary care is the ideal arena to achieve high-impact prevention strategies such as healthy eating, healthy weight, physical activity and exercise. Joint pain itself reduces physical activity. The multidisciplinary team including general practitioners, practice nurses, physical therapists, occupational therapists, podiatrists and community pharmacists, is in a crucial position to provide support for self-management, especially for interventions related to exercise and behavioural change (Dziedzic et al., 2009). These interventions are complex and need to be embedded in the patient's own experiences, informed by lay knowledge of living with joint pain, and discussed as part of all consultations (Morden et al., 2011; Grime and Dudley, 2014).

10.2 OA in secondary care: the role of the rheumatologist

Only a small proportion of patients with OA may be referred to secondary care, and ultimately see a rheumatologist, with the majority of patients being managed in primary care. Furthermore, patients referred because of complex OA to rheumatologists in Europe may only be seen on one occasion, with therefore no implementation or initial monitoring or adjustment of a suggested management plan. Regular review of patients with OA is clearly important and recommended among others by NICE. With this in mind, what is the role of the rheumatologist for the patient with OA? We would suggest the following:

1. Work with primary care colleagues to suggest local guidelines for referral, such as management of 'complex cases', patients with diagnostic uncertainty, or patients in need of specialist adjunctive services such as occupational or physical therapy that are not available in the community.
2. Rheumatologists are experts in musculoskeletal medicine. It is unrealistic to expect all primary care practitioners to know about the range of treatments listed in this module and the evidence behind them. Use opportunities to support primary care colleagues in the treatment of patients with OA. This might include, but not be limited to:
 1. Education and update sessions for primary care. It is of particular importance to highlight the range of, and evidence base for, non-pharmacological treatment options available.
 2. Detailed plans for individual patients. If local policies do not permit follow-up of patients with OA in secondary care, suggest monitoring and adjustments to the management plan in correspondence with primary care.
3. Consider OA patient pathways in your region. To what potential services might patients with OA be referred? Are all services connected and offering consistent messages about OA care? Are any third sector agencies involved or being utilised?

OA is a leading cause of morbidity and disability and rheumatologists have the skills and expertise to manage these patients effectively. This may be regarded as the real challenge for rheumatologists in the future. As rheumatologists may only see a small proportion of these patients in practice, it remains the rheumatologist's responsibility to act as an advocate for patients with OA.

SUMMARY POINTS

- Recent evidence-based guidelines concur with respect to the objectives and principles of management of patients with knee, hip or hand osteoarthritis (OA) and on the core therapy that should be considered for anyone with OA. The guidelines also agree, with only minor variation, on the many adjunctive options that should additionally be considered and advised for individual patients.
- There is research evidence to support many of the recommended treatments for OA, but expert and patient opinion are equally important forms of 'evidence', especially given the caveats and limitations of most RCTs and the difficulty of blinding and/or using placebo/sham interventions of physical treatments or surgery. In determining the strength of recommendation for any treatment, many factors other than efficacy need to be considered, including safety, cost, logistics of delivery, acceptability and the individual patient's preferences.
- A multifaceted, individualised package of care should be devised with the patient and subsequently monitored and adjusted as necessary. The non-specific benefits of treatment should not be ignored or underrated, but fully optimised.
- The objectives of management are: (1) patient education and information access; (2) pain relief; (3) optimisation of function; and (4) beneficial modification of the OA process.
- The core treatments that should be considered for every patient with OA are: (1) patient education and information access; (2) exercise— both generalised aerobic fitness training and local neuromuscular training, strengthening and range of motion exercise; and (3) reduction of adverse mechanical factors—for example, weight loss if overweight/obese, appropriate footwear, pacing of activities. Recent audits suggest that these core aspects of management are often omitted.

- Topical NSAIDs are recommended as a first line analgesic. Paracetamol may be used at conservative dosing and duration, although it is less effective and has greater risk than previously thought.
- Other pharmacological adjuncts for pain control include topical capsaicin, oral non-steroidal anti-inflammatory drugs (including COX-2 selective agents) and opioids. An additive rather than substitutive approach is recommended, with due regard to problems of polypharmacy.
- Intra-articular injection of glucocorticoid is recommended for short-term control of pronounced pain. There is much less support for intra-articular injection of hyaluronan.
- Other biomechanical approaches that are recommended include walking aids, braces, splints and assistive devices.
- Other physical treatments that are recommended include thermotherapy and use of TENS (transcutaneous electrical nerve stimulation).
- Currently no drug is recommended for disease modification of OA. Glucosamine sulfate, chondroitin, diacerein and others are regarded as relatively safe but have limited support for adjunctive pain relief. Hydroxychloroquine cannot currently be recommended and methotrexate remains under evaluation.
- Treatment of comorbidity, such as depression, is important. Low-dose amitriptyline at night is recommended in patients with pain and non-restorative sleep. Duloxetine has beneficial effects on pain.
- Surgery, including total joint replacement, should be considered for patients who have persistent pain, stiffness and reduced function that are refractory to non-surgical treatments and which impact significantly on their quality of life. Patient-specific factors such as age, obesity or other comorbidity should not be barriers to surgery, and referral should be made before there is prolonged and established functional limitation and severe pain, though continued nonsurgical management with appropriate ongoing clinical review can also be considered.
- Many patients with OA will not ultimately see a rheumatologist and rheumatologists should consider opportunities to support primary care in the management of these patients.

IN-DEPTH DISCUSSION I

Exercise for OA

Exercise is a central core component of OA management. Here we will consider:

- the general benefits of regular activity
- the decline in muscle function in OA
- evidence for exercise in management of OA
- practical considerations relating to delivery of exercise

General benefits of exercise and regular physical activity

There are many health reasons to promote regular physical activity (Fig. 20). For example, it associates with increased life expectancy and reduces risk of cardiovascular disease, diabetes, obesity, osteoporosis and certain cancers (Fentem, 1994). In the elderly, regular exercise may slow or even reverse age-related changes such as decline in muscle bulk and strength (Beudart et al., 2017), balance (Howe et al., 2011) and is one component of falls prevention (NICE, 2013). Furthermore, regular exercise in people with OA improves mental health and encourages restorative sleep, well-being and quality of life (O'Reilly and Doherty, 2001; Tanaka et al., 2015), though the effects on mental health in the wider population are less clear (Penedo and Dahn, 2005).

Fig. 20. Regular physical activity has many health benefits

Rationale for exercise for OA - decline in strength and fitness in OA

People with knee OA often show reduced quadriceps and hamstring strength, impaired balance and proprioception and a tendency to fall. Weakness in OA may result from muscle atrophy (predominantly type II fibres), reflex spinal cord inhibition or voluntary inhibition due to pain. Quadriceps weakness associates with severity of pain and disability in knee OA and may be a predictor of adverse outcome. Also, symptomatic medial compartment knee OA is associated with reduced strength in all muscle groups at the hip (Hinman et al., 2010). Although most data relate to knee OA, in principle reversible decline in muscle health is a therapeutic target for OA at any joint. In addition to impairments in motor and sensory function, people with

OA have reduced cardiovascular fitness compared to age- and sex-matched controls. Therefore, there is a clear logic to support both neuromuscular training/strengthening and aerobic exercise as a treatment for OA (Zhang et al., 2008; Zhang et al., 2007; Fernandes, 2013; McAlindon, 2014; NICE, 2014) although referral for exercise is offered in only 39% consultations (Hagen et al., 2016).

Evidence for exercise in OA

Exercise may slow the progression of OA in several ways and moderate daily exercise does not increase risk of hip or knee OA (Lefèvre-Colau et al., 2016). Moderate to high quality evidence shows that land-based exercise offers short term benefits for knee pain and function sustainable 2-6 months after cessation (Fransen et al., 2015).

Exercise increases glycosaminoglycan content in cartilage of patients at risk of knee OA (Roos and Dahberg, 2005), increases the chondroprotective cytokine IL-10 both intra- and periarticularly in symptomatic knee OA (Helmark et al., 2010) and promotes muscle protein synthesis in old individuals with knee OA (Petersen et al., 2011). The benefits of exercise for knee OA are supported by a systematic review and meta-analysis of 13 RCTs undertaken in 2005 (Roddy et al., 2005a) and by a review of systematic reviews (Jamtvedt et al., 2008). Pooled effect sizes (ES) for pain relief are moderate for both aerobic (ES=0.52, 95% CI 0.34, 0.70) and strengthening exercises (ES=0.32, 95% CI 0.23, 0.42) and ESs for self-reported disability are 0.46 (95% CI 0.25, 0.67) for aerobic and 0.32 (95% CI 0.23, 0.41) for strengthening exercise (Roddy et al., 2005a). In symptomatic knee OA, both weight bearing and non-weight bearing exercises associates with improvement in physical function (Bruyere, 2009). The mean (95%CI) decline in WOMAC 3 days after completing an 8 week exercise regime was -10.3 (-8.5 to -12.2) for the weight bearing and -17.2 (-14.6 to -19.8) for the non-weight bearing group (Bruyere, 2009). The benefits of exercise are substantially greater than the small (clinically insignificant) benefits of paracetamol, long recommended as a first-line pharmacological treatment for OA, as reported in a systematic review and network meta-analysis (Machado et al., 2015) and also greater than oral NSAIDs (Zhang et al., 2010) .

Exercise in knee OA can improve the amount of time spent walking, gait speed and distance walked (Tanaka et al., 2016) and Tai Chi, balance and proprioceptive exercises are also beneficial (Anwer et al., 2016). Compared with surgery, exercise therapy and meniscectomy showed comparable results but exercise after meniscectomy showed benefit on function in the longer term (Swart et al., 2016).

Aquatic therapy can also be an effective and safe adjunctive treatment for knee OA (Lu et al., 2015). Well-structured water based exercises with appropriate intensity and control of overload can be effective in improving physical function and increasing muscle strength (Mattos et al., 2016). There are less data for hip and hand OA (Valdes and Marik, 2010), although two RCTs of water-based exercise for hip OA report pain relief (ES=0.25, 95% CI 0.02, 0.47) and reduced stiffness (ES=0.17, 95% CI 0.05, 0.39) (NICE, 2008; Zhang et al.,

2008). A meta-analysis of RCTs showed that even land based exercise regimens show a small treatment effect for pain (standardized mean difference= -0.38, 95% CI -0.09 to -0.67) but not for physical function in hip OA (standardized mean difference= -0.02, 95% CI -0.31 to 0.28) (Fransen et al., 2010). The Ottawa panel has recommended land based therapeutic exercise strength training for hip OA (Brosseau et al., 2016).

A network meta-analysis comparing different packages of exercises for lower limb OA, predominantly knee OA, demonstrated that combinations of exercise to increase strength, flexibility, and aerobic capacity are likely to be the most effective (Uthman et al., 2013). A recent study of hand exercises delivered in classes by occupational therapists demonstrated that hand exercises were cost effective (Oppong et al., 2015), though a Cochrane review of exercises for hand OA determined that the quality of evidence was generally low but that benefits of exercise were small for pain in hand OA and the effect on quality of life was uncertain (Østerås et al., 2017).

As mentioned above, knee OA is associated with weakness in hip muscles. It may therefore be advisable to encourage hip muscle strengthening exercises in individuals with knee OA. In a pilot study, hip abductor muscle strengthening reduced knee pain and knee load (measured as the external adductor moment at the knee) (Thorp et al., 2010). However, in a RCT of hip abductor and adductor strengthening in individuals with varus knee OA, there was a significant reduction in knee pain and improvement in knee function, but no change in knee load, suggesting the presence of other mechanisms (Bennell et al., 2010). Limitations in interpreting the research evidence include the short duration of RCTs (only two have gone to 18 and 24 months); variability in type, frequency and intensity of exercise regimens; and variation in delivery (e.g. home versus hospital, individualised or group-based). When compared directly, strengthening and aerobic exercise show equivalent benefits (Roddy et al., 2005a).

Despite heterogeneity of RCT interventions, current guidelines strongly support both strengthening (neuromuscular training) and aerobic fitness exercise for OA, especially knee or hip OA (Roddy et al., 2005b; Zhang et al., 2007; Zhang et al., 2008; NICE, 2014). Exercise appears safe, with no reported pain exacerbation in patients with OA (Roddy et al., 2005b). Long term (three to 30 months) low-impact therapeutic exercise has been found, in a systematic review, to be safe for older adults with knee pain; there was no evidence of increase in pain or decrease in physical function, radiological progression of OA, nor an increase in total knee replacements (Quicke et al., 2015).

Provided trauma is avoided, moderate exercise does not lead to acceleration of knee OA, whether or not there is evidence for pre-existing disease (Bosomworth, 2009; Quicke et al., 2015). There is not complete consensus on conditions that represent a clinical need to restrict exercise or form an absolute contraindication. Aerobic activity benefits comorbidities commonly occurring with OA. A helpful starting

point to consider exercise restriction or contraindication is the narrative review by de Rooij et al. (2013), who list various cardiac and metabolic conditions as absolute contraindications and additional reasons for restriction of exercise.

Considerations relating to the practical delivery of exercise to people with OA

As with OA management overall, a key principle is to individualise the exercise programme. Delivery methods vary in terms of local availability or quality and some patients enjoy group activities whereas others do not, so both local factors and patient choice require consideration. Any programme should start at a low frequency, duration and intensity appropriate to the patient's capabilities, and then slowly increase to allow physiological adaptation. "Small amounts, often" is appropriate and mirrors the principle of pacing of general activities. There is a helpful introduction to the health benefits of exercise and, specifically, advice about the principles involved in starting exercise (Chapter 16) at the (UK-focussed) Motivate2Move website (<https://gpcpd.walesdeanery.org/index.php/welcome-to-motivate-2-move>).

A systematic review by Juhl et al. (2014) identified that programmes with exercises of a single type were more effective than those with mixed types (effect size for pain reduction 0.61 in trials examining a single exercise type compared to 0.16 for mixed types).

For muscle strengthening it is common to start with isometric exercises which tighten the muscle without moving the joint, thus avoiding impact loading.

Straight-leg raising while sitting or lying (Fig. 21) or pushing the knee into extension on the bed are common starting quadriceps exercises (Fig. 22).

Fig. 21. Patient being instructed on a straight-leg raise, keeping the foot dorsi-flexed to focus contraction on the quadriceps.

Fig. 22. Patient being instructed to push the knee down hard onto a soft object on a bed, again with foot dorsi-flexed.

Each manoeuvre is held for 5-10 seconds before relaxing, and then repeated after a short rest. These exercises are easily done while watching television or lying in bed and can be gradually progressed in terms of numbers of contractions in each cycle and numbers of cycles/day, or by putting weights (e.g. a cushion) on the foot. 'Range of motion exercises' are useful for "warm-up" prior to isometric exercise.

More dynamic exercises, which strengthen muscles while moving the joint, can be added in, for example, step-ups (Fig. 23), walking, cycling, swimming, dancing, or exercising on a variety of machines in the home or at a gym. Resistance training is beneficial in reducing pain and stiffness and improving function in knee OA (Li et al., 2016).

Fig. 23. Stepping up and down a stair – this has an aerobic component if prolonged.

Patients who enjoy cycling should use a raised seat so the knee is not too flexed when pushing down (to avoid undue patello-femoral stress). Such dynamic exercises increase the efficiency of co-ordinated movement (neuromuscular training) and often merge with aerobic exercise. Aerobic exercise causes the heart and lungs to work harder than at rest and is recognized by an increase in pulse, increased respiratory rate and sweating.

The ESCAPE-PAIN programme integrates education about self-management and coping strategies with an individualised exercise regime. Benefits on function from this programmes have been identified in a randomised controlled trial (Hurley et al., 2007).

Adherence to exercise regime is important to pain relief and physical function at 5 years (Pisters et al., 2010). Clearly, it helps adherence if the patient selects an activity that they enjoy. It is also useful to link home exercise to a regular activity (e.g. prior to a morning shower) so it becomes part of the daily routine. A meta-analysis with high heterogeneity offers some evidence for no difference between outpatient versus home exercises in short term improvement in physical function and knee ROM (Florez-García et al., 2016; Jansons et al., 2016). Other strategies to improve adherence include keeping a diary, telephone monitoring, and involvement of spouse and friends (Roddy et al., 2005b). Trained therapists and practitioners (e.g. physiotherapists, occupational therapists, practice nurses, swimming bath and health club trainers) can advise on appropriate exercises, starting levels and rates of progression, and often give important positive feedback. Therapist-delivered pain coping skills training can also augment exercise (Bennell et al., 2015). A recent systematic review of adherence interventions in people with arthritis concluded that there was only limited evidence for any such intervention (Ezzat et al., 2015), though an earlier, Cochrane, review identified positive benefits to adherence from the use of specific strategies to enhance adherence (such as the use of goal-setting, feedback, reinforcement, diaries, pedometers); supervision; the use of refresher or 'booster' sessions; additional tools such as audio- or video-tapes to supplement supervision; and incorporation of exercise into self-management programmes (Jordan et al., 2010).

There is no agreement over the minimum effective "dose" of strengthening or aerobic exercise for OA but benefits from land-based therapeutic exercises for knee OA can be sustained for at least 2-6 months after cessation of formal treatment (Fransen et al., 2015). In general, the more the better but the frequency and intensity depend on the individual. Juhl et al. (2014) identified that better results were obtained in programmes that were supervised and had at least three sessions per week with at least 12 supervised sessions. Once exercise has been successfully adopted by the patient, enquiry concerning ongoing exercise should occur at each patient review to reinforce the importance of exercise maintenance (Bennell et al., 2014), and the safety of this long term (Quicke et al., 2015).

Osteoarthritis: treatment

John Edwards, Zoe Paskins, Krysia Dziedzic

A previous version was coauthored by Zoe Paskins, Krysia Dziedzic, Burkhard Leeb

IN-DEPTH DISCUSSION II

Intra-articular injection of corticosteroid in OA

Intra-articular (IA) injection of corticosteroids is widely recommended for short-term control of marked pain in OA. Here we will consider:

- the evidence for efficacy of IA corticosteroid in OA
- pharmacology of injectates and possible mechanisms of action
- predictors of response, and
- indications, contraindications and possible side-effects

Evidence for efficacy of IA corticosteroid in OA

IA injection of corticosteroid, first proposed by Hollander over 50 years ago, is a widely used and valued therapy for OA. Although current guidelines recommend use of IA steroid for knee, hip and hand OA, relatively few RCTs have examined this treatment. Historically, the support in guidelines has reflected widespread clinical confidence in this treatment. Universal experience suggests that benefit from IA steroid can appear very quickly, usually within 24 hours, and that in some individuals benefit may last several weeks or even a few months.

A Cochrane systematic review undertaken in 2015 examined 27 randomised or quasi-randomised controlled trials that compared IA corticosteroids with sham injection or no treatment in people with knee osteoarthritis (Juni et al. 2015). This review reported a modest effect of IA corticosteroid on pain 1 to 2 weeks after treatment (Standardised Mean Difference SMD -0.48, 95% CI -0.70 to -0.27), small to moderate effect at 4 to 6 weeks (SMD -0.41, 95% CI -0.61 to -0.21), small at 13 weeks (SMD -0.22, 95% CI -0.44 to 0.00) with no evidence of an effect at 26 weeks. Similar results were found for physical function, although no effect was seen at 13 weeks. However, the review concluded that the benefits of IA corticosteroids were unclear due to low methodological quality and heterogeneity of the included studies.

There are five RCTs of IA corticosteroid for hip OA, three of which used fluoroscopic guidance (Lambert et al. 2007, Kullenberg et al. 2004, Flanagan et al. 1988) and two of which used ultrasound guidance (Qvistagard et al. 2006, Atchia et al. 2011). The two most recent studies demonstrated significant relief of both pain and function at eight weeks post injection (Lambert et al. 2007, Atchia, et al. 2011). Qvistagard et al. (2006) measured outcomes at three months but found no significant difference in pain or function at this point. However, two other studies have demonstrated difference in outcomes at 3 months; Kullenberg et al. (2004) reported significant pain reduction at 12 weeks and Lambert et al. (2007) reported significantly more WOMAC20 responders in the steroid treated group at 3 months.

Individual RCTs comparing IA corticosteroid injection vs placebo for thumb-base trapeziometacarpal (TMC) OA have not demonstrated any difference in outcomes at time points from 4 to 26 weeks (Meenagh et al. 2004, Heyworth et al. 2008). However, data from a randomised trial comparing IA triamcinolone with HA did

demonstrate beneficial effects of IA corticosteroids on pain, grip strength and hand function, persisting for 6 months (Bahadir et al. 2009). A more recent systematic review and meta-analysis of placebo controlled studies reported no effect on pain relief at 24-26 weeks (Kroon et al. 2016). This review also identified one study comparing IA corticosteroid with placebo for painful interphalangeal OA, which has a low risk of bias and reported beneficial effects on pain during movement and swelling. The acromioclavicular joint and first metatarsal-phalangeal joint are further examples of commonly injected sites where evidence of efficacy is largely anecdotal.

There are many caveats to the interpretation of studies of IA corticosteroid injection in OA. All the studies generally have low numbers of participants; for example, the hip trials mentioned above recruited between 36 and 104 patients with just 12 to 40 participants receiving steroid injections. The control groups for these studies also vary with some using saline injection as control, and others using local anaesthetic alone. Some RCTs have an additional intervention group of hyaluronan injections; in these studies the steroid treated groups have had additional 'sham' injections (Qvistgaard et al. 2006, Heyworth et al. 2008). Studies vary in their use of imaging to guide injections and the population that have been recruited, with most studies recruiting from secondary care where patients may have more severe disease. Furthermore, the dose of steroid varies between studies and may not reflect usual practice.

Pharmacology of injectates

Commonly used preparations for IA injection are long acting hydrophobic steroids such as methylprednisolone acetate, betamethasone acetate, triamcinolone hexacetonide and triamcinolone acetonide. All may be detected in synovial fluid 1-2 weeks after injection (Fig. 24), triamcinolone products possibly persisting the longest. A Cochrane review suggests that IA triamcinolone hexacetonide is twice as effective as IA betamethasone for pain relief at 4 weeks (RR 2.00 95%CI (1.10 to 3.63)) (Bellamy, 2006) with a further systematic review suggesting triamcinolone hexacetonide has a quicker onset of action than methylprednisolone (Garg et al. 2014). The dose of injectate is also important: Robinson and colleagues demonstrated marked difference in outcomes relating to stiffness and disability at 12 weeks when comparing 40 mg with 80 mg of IA methylprednisolone for hip osteoarthritis (Robinson et al. 2007).

There is no general consensus regarding the frequency of administration but in general the longer the interval between injections the better. One RCT comparing safety and efficacy of IA steroid versus IA saline given every 3 months for two years showed no apparent detrimental effects (Raynauld et al. 2003).

Fig. 24. Steroid particles in knee synovial fluid identified one week after injection.

Mechanism of action

Although there is little research data, experience suggests that aspiration of a swollen joint may quickly relieve pain by reducing intra-articular hypertension and that injection of a long acting steroid may prevent re-accumulation of fluid and reduce synovial inflammation. The precise mechanisms are incompletely understood, but the most relevant effects of IA steroid are likely to be on synovial membrane, with reduction of lymphocyte and macrophage activity, decrease of inflammatory mediators such as prostaglandins, collagenases and cytokines and limitation of vascular permeability. The latter may be in keeping with the observed reduction of effusion. IA steroid may also diffuse into peri-articular tissues and give additional symptom benefit at these sites.

Predictors of response

Predictors of response may be considered in terms of disease or patient specific characteristics or treatment specific characteristics. First, we will consider the specifics of treatment.

Various studies have evaluated the accuracy of blinded injections and concluded that accuracy associates with efficacy (Jones, 1993). In recent years, as the use of musculoskeletal ultrasound has become more common, a number of studies have evaluated the impact of ultrasound on both accuracy and efficacy. Ultrasound guidance increases the accuracy of IA corticosteroid injections, although blinded injections of the knee using the superolateral patellar approach have been reported as having accuracy of 87% (Maricar et al. 2013a). For IA in OA, there is, as yet, limited evidence demonstrating superior clinical efficacy and cost effectiveness to support the use of ultrasound guided injections; however, a recent systematic review suggests a short term benefit in injections of the knee (Maricar et al. 2013a).

Other treatment specific predictors of response include the type and dose of steroid which have been discussed in the sections above.

In terms of disease specific predictors, it would seem logical to consider that patients with a marked inflammatory component to their OA would have better outcomes with IA corticosteroid. Correct intra-capsular placement can influence the benefit obtained and knees with effusions may be easier to aspirate and associate with more accurate injections. However, studies that have evaluated the role of synovitis and effusion in predicting response in knee and hip OA have shown conflicting results. A systematic review of predictors to response in knee injections included studies that had evaluated the association of effusion, synovitis, structural damage, and aspiration with outcome, and concluded that there were no consistent predictors (Maricar et al. 2013b).

In studies evaluating predictors of outcome following hip injection, radiographic severity of disease and lower BMI have been associated with improved outcomes (Desmukh et al. 2011, Robinson et al. 2007,). The presence of synovitis and has been associated with improved outcome in one study (Atchia et al. 2011), but the presence of effusion was not predictive of outcome in two other studies (Qvistgaard et al. 2006, Robinson et al. 2007).

Most studies of IA have not been designed to evaluate predictors of response, and it is perhaps not surprising that the studies have yielded conflicting results, given the small numbers of participants. Hirsch et al. (2013) reviewed the evidence for predictors of response in knee and hip injections and concluded that important psychological predictors had been infrequently studied; ongoing studies are aiming to evaluate the role of psychological factors such as the presence of anxiety and depression in predicting outcomes in OA corticosteroid injections.

Indications and clinical application

The main indication for IA steroid injection is to control moderate to severe pain. In clinical practice such quick control of significant pain is very useful. It can also give the patient confidence and optimism concerning their OA and increase adherence to other OA treatments. Although some guidelines emphasise possible better benefit in patients with an effusion or an inflammatory “flare”, IA injection should not be restricted to such patients. Two additional indications for IA steroid injection are: [1] for the florid inflammation of acute calcium pyrophosphate crystal arthritis (CCPD, formerly: pseudo gout), which can associate with OA, especially knee OA in older patients; and [2] for an associated popliteal cyst to temporarily reduce synovial fluid production (usually administered by the anterior route rather than directly into the cyst).

Contraindications

The main contraindication to IA steroid injection is local infection or cellulitis. As with venepuncture, anticoagulation therapy is not a problem as long as anticoagulation is within the therapeutic range, the procedure is as non-traumatic as possible, and more prolonged pressure is placed over the puncture site following needle withdrawal. IA steroids are not recommended for haemarthrosis complicating OA or for complications such as true locking or internal derangement.

Side-effects

In general, IA steroid injection is a very safe treatment, assuming that basic aseptic precautions are observed (Courtney and Doherty 2005). Although septic arthritis is a serious potential side-effect this appears to be extremely rare. In practice, the more common side-effects are:

- Uncomfortable **facial flushing**, observed in about 10% of patients, mainly women, the day after the injection and lasting just 24-72 hours. It may be more common with triamcinolone but is largely constitutional and likely to recur with repeat injections.
- **Post-injection flares** (<5%), usually beginning shortly after injection and subsiding within several hours. These may reflect crystal-induced inflammation from corticosteroid ester crystals but also occur following injection of saline placebo.
- **Subcutaneous atrophy**, sometimes with depigmentation or telangiectasia, at the site of steroid injection (< 1%). This is mainly limited to injection of steroid into small joints or superficial periarticular structures. Triamcinolone is the main culprit and non-fluorinated steroid is recommended for small joint and periarticular injections.
- **Temporary worsening of diabetic control**, usually for just 24-72 hours. As long as the patient is forewarned this is not usually a clinical problem.

A theoretical risk to consider with multiple injections is the risk of steroid induced atrophy of cartilage and bone; a recent trial examining the effect of three monthly IA corticosteroid injections in knee OA, over a two year period, did report significant reductions in cartilage volume in the corticosteroid treated group (McAlindon et al. 2017). There is more evidence to suggest chondrotoxicity as a result of intraarticular local anaesthetic which is often coadministered with corticosteroid: lidocaine-induced chondrotoxicity arises from intra-articular infusions of local anaesthetic in a post-surgical setting, and there is evidence of a chondrotoxic effect from a single injection in animal studies (Gulihar et al. 2015). Finally, there has been concern that injections prior to joint replacement surgery may predispose to post-operative infection but this risk has not been confirmed by a recent systematic review (McMahon et al. 2013).

Low back pain and associated syndromes

David Walsh

A previous version was coauthored by Federico Balagué, Maximilian Schindler, Stéphane Genevay, Francois Rannou, Serge Poiraudau, Yves Henrotin, Christelle Nguyen

LEARNING OBJECTIVES

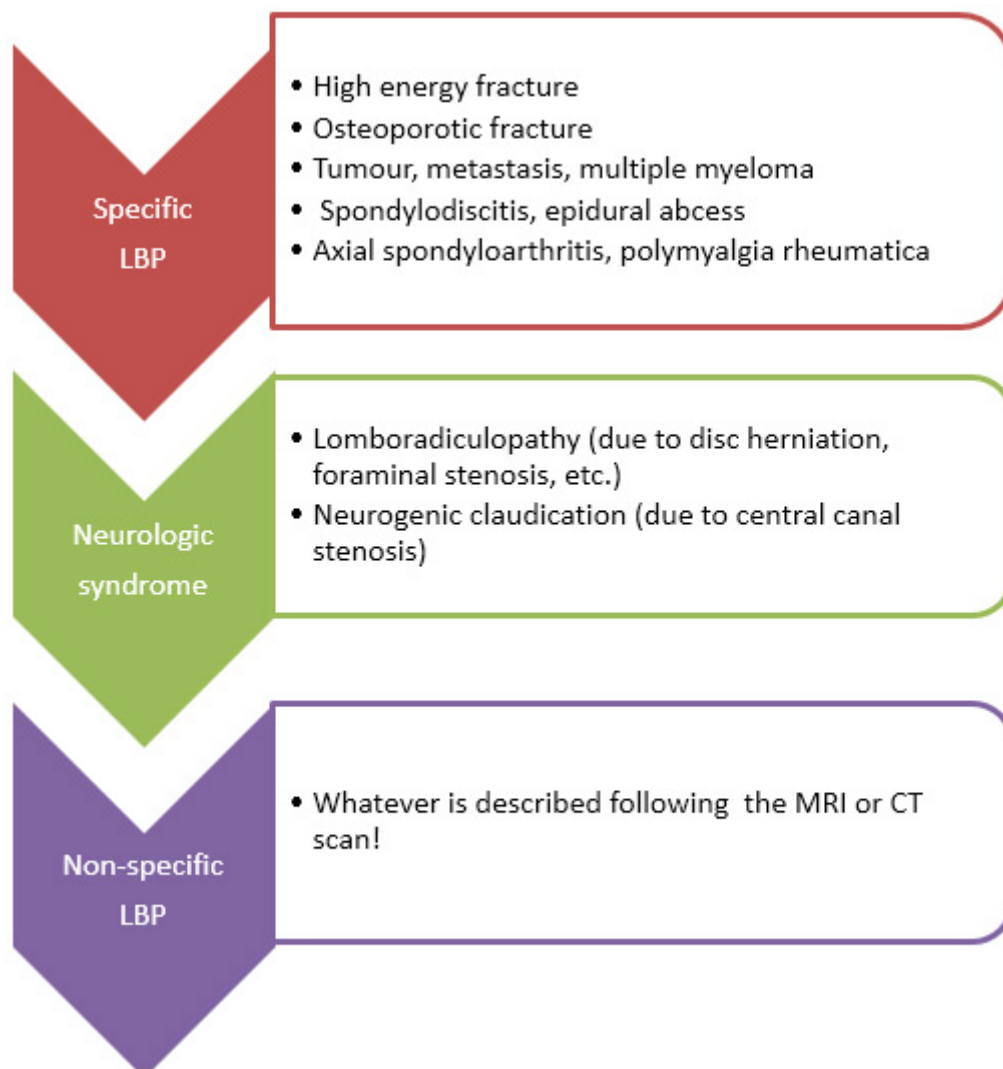

- Identify patients at risk of specific low back pain (LBP) and act accordingly
- Demonstrate knowledge of the current view of the epidemiological data and evolution of LBP
- Display a basic understanding of current theories related to non-specific LBP
- Recognise how chronicity develops in LBP and the associated main factors
- Describe the specificities related to the evaluation of patients with LBP
- Manage acute and chronic LBP based on an evidence-based approach
- Understand the value and limitations of radiological imaging in managing LBP (eg, idiopathic scoliosis, Scheuermann's disease, spondylolysis, etc)
- Identify and manage neurological syndromes originating in the spine (cauda equina syndrome, radiculopathy and neurogenic claudication)
- Discuss the benefits and limits of surgical intervention, depending on the syndrome

1. DEFINITION AND EPIDEMIOLOGY OF LOW BACK PAIN

Low back pain (LBP) is defined as pain related to the area between the lower ribs and the gluteal folds, with or without non-neuropathic leg pain, and is traditionally considered to affect a vast number of people (70–80%) at least once in their life (Balagué et al, 2012*). It affects people of all ages.

LBP is primarily a symptom encompassing several subgroups of diseases. It may be due to specific medical causes (<5%) or neurological syndromes (10%), but it is usually classified as non-specific LBP in most patients (figure 1). Non-specific low back pain has been defined as that which is not due to cancer, fracture, infection or an inflammatory disease process (*Ward et al, 2016), and the term 'non-specific' is not intended to indicate a lack of understanding of underlying pain mechanism.

Picture 1: Classification for low back pain (LBP)

The annual incidence of non-specific LBP (defined as a first episode in subjects reporting no previous symptoms or as incident pain after a pain-free period) is about 25% (Taylor et al, 2014). The figures were

similar in community-based or occupational populations. A longitudinal study based on SMS Track reported that almost two-thirds of subjects had LBP during a 1-year follow-up (Leboeuf-Yde et al, 2013).

The global burden of LBP is substantial, due to its impact on quality of life (Hoy et al, 2014). Despite limitations in the evidence, LBP ranked first out of 291 conditions studied for the number of years lived with disability, and sixth for disability-adjusted life-years. These elements explain the tremendous socioeconomic impact of LBP. Relationships with occupational activities are far from straightforward (Driscoll et al, 2014). Many people with non-specific LBP also report pain in several other musculoskeletal sites, as well as more or less non-specific symptoms unrelated to the musculoskeletal system—for example eczema, constipation, diarrhoea, dizziness, sleep problems, tiredness (Hartvigsen et al, 2013).

LBP is usually classified as acute, subacute and chronic according to its duration. LBP is considered 'acute' when it lasts from 1 day to <6 weeks, 'subacute' if it is present for 6 to <12 weeks, or 'chronic' when it is present for ≥ 12 weeks (van Tulder et al, 2006). Relapses are frequent, and 'recurrent' LBP has been defined as a new episode after a symptom-free period of 6 months (Balagué et al, 2012*). An alternative classification of LBP depends on pain trajectory; those who recover, those with a fluctuating pattern, and those with persistent back pain (Axén and Leboeuf-Yde, 2013). Improvement generally occurs during the first month following new onset LBP, but only a minority of people with persistent pain at 1 month might be pain free at 1 year. Factors that predict worse pain prognosis include higher disability, psychological characteristics such as catastrophizing, anxiety or depression, and more widespread pain (radiating into the legs, or also experienced in neck or shoulder) (*Hill et al., 2011). Almost half of people suffering an episode of LBP might not seek medical care (Ferreira et al, 2010) and public information might be equally important as is professional advice to ensure that people manage their LBP optimally.

2 Source of pain in non-specific LBP

The pathophysiology of non-specific LBP is largely unknown. Multiple spinal tissues might contribute to LBP, and heterogeneity between and within individuals makes diagnostic sub classification challenging. Treatments directed at a specific pathology should be of greatest benefit to those whose pain is caused by that pathology, and people with more severe symptoms have greater potential to benefit from an effective treatment. Stratification of patients according to pathology or severity is therefore logical, although treatment effects that clearly differentiate between classification groups have been difficult to prove, and many treatments for LBP (e.g. analgesic drugs and cognitive behavioural therapy) are generally applicable.

Since the discovery of disc herniation in 1934, back pain has been mainly related to lesions of the spine. This straightforward and common sense theory gained much acceptance during the 1970s and 1980s with the development of imaging technologies, such as computed tomography (CT scan) and magnetic resonance imaging (MRI), which emphasised the range of pathology occurring in the spine. However, neither acute nor

chronic LBP can be clearly related to these radiographic findings. A prospective study in an asymptomatic population showed that MRI repeated at the time of the first acute episode was identical to MRI performed at inclusion in the study, even in patients with severe episodes of pain and disability (Carragee et al, 2006). Numerous studies highlight the extremely high percentage of 'pathological' findings in the normal asymptomatic population (Takatalo et al, 2012; Steffens et al, 2014*), including discopathy (eg, reduced signal on T2 weighted MRI images; black disc, reduced disc height, marginal osteophytes, bulging discs, disc herniations, facet joint osteoarthritis, spondylolisthesis and annulus fibrosus tears. This clearly reduces the specificity of imaging studies. In a meta-analysis, the authors concluded that although some of these imaging findings were statistically more common among patients with chronic LBP, there was no clinical significance at the individual level since the frequency in the normal population was so high compared with the difference between the two populations (Steffens et al, 2014*).

Discs, facet joints and sacroiliac joints are each considered possible discrete sources of LBP. However, clinical tests and imaging have not definitively been shown to predict outcome from specific treatments directed at these structures (Hancock et al, 2007, Mars et al., 2015). Malik et al (2013). Anatomical classification of LBP with refined tools might yet be appropriate, and the current sparsity of supporting evidence might reflect the frequently mixed pathology in LBP, lack of specificity of clinical tests, and disappointingly low efficacy of interventions.

'Spinal instability' has been proposed as a mechanism for LBP (Panjabi et al., 1989). Gross instability due to major structural lesions (eg, fractures, tumours or infections) might certainly benefit from surgical stabilisation. Clinicians report symptoms and signs of spinal instability, radiologists describe signs of spinal instability on X-ray and MRI reports, physiotherapists use techniques to increase spinal stability and surgeons operate on patients because of spinal instability. However, many studies have highlighted the lack of a relationship between these different uses of the same concept. For example, patients with clinical signs of spinal instability do not have the features that the radiologists describe as associated with spinal instability, and neither one nor the other have ever been related to a modification of the neutral zone (Reeves et al, 2007*). Irrespective of whether 'spinal instability' is a major source of LBP, increased pain during spinal movement clearly indicates a biomechanical component. However, prevention of movement in a spinal segment by surgical fusion does not necessarily lead to pain relief, possibly suggesting other causes of pain.

Many patients can identify a specific moment or activity that initiated their LBP, but in most cases, acute LBP resolves spontaneously, regardless of the treatment. The mechanisms by which LBP might become chronic are incompletely understood, but chronic pain does not inevitably indicate persistent damage. Current evidence suggests that, far from damaging the back, maintaining activity during an acute episode of LBP facilitates effective repair. Bed rest is believed to be counterproductive. Maintaining activity might help restore strength and proprioceptive reflexes, reducing the risk of re-injury.

Inconclusive evidence from attempts at diagnostic classification based on imaging need not necessarily preclude a structural origin for LBP. Structural or biomechanical changes that cannot be easily imaged might mediate the weak associations between radiographic findings and LBP. Biomechanical factors such as sub failure magnitude loads might contribute (Rainville et al, 2011*). A non-injury model of LBP has been proposed (Indahl et al, 1998; Sorensen et al, 2010; Rainville et al, 2011*). In this model, pain arises from a complex interaction between the nerve receptors within the connective tissues of the spine and abnormal paraspinal muscle function or tension might be sufficient to explain symptoms. Lumbo-pelvic kinematics—range, speed and precision of movement, and proprioception—are modified in patients with LBP. Slight disorganisation of muscle function, demonstrated by surface electromyography during repetitive standing tasks, might predict the development of LBP in previously pain-free individuals (Holm et al, 2002*), and might be reduced after successful rehabilitation programmes.

If classification of LBP is to have clinical value, it should be matched to effective treatment. Each of the many proposed classifications is intended to predict benefit from a specific form of treatment. Classification should help explain why treatments work, complementing evidence from randomised controlled trials that they do indeed work. Analgesia following medial branch block should predict benefit from denervation. Exercise might improve strength and proprioception where they are deficient, even though pain might occur during the exercise. Helping patients to make sense of the benefit of treatments such as exercise will help them to accept and adhere to it.

3 Chronicity

3.1 Peripheral sensitisation

Despite the only weak association between imaging findings and reported pain, several observations point to peripheral mechanisms in chronic LBP. Pain is typically dependent on position and movement and blockade of afferent input (e.g. by nerve block or radiofrequency denervation) can reduce pain severity at least in some patients. Mechanisms in the periphery might drive pain even in the absence of ongoing injury, due either to structural or functional changes in the spine. Inner regions of intervertebral discs are not normally innervated. When nerves have grown into these structures as a part of the repair process (Freemont et al., 1997), it might be expected that they will become sensitive to normal biomechanical loads. Altered biomechanics in the spondylotic spine, for example increased forces transmitted through vertebral end plates due to changed properties in the intervertebral disc, might also lead to neuronal activation during normal activities. Peripheral sensitisation produces increased afferent signalling in response to a standard stimulus, and may be mediated by altered ion channel expression in primary afferent neurones. Nerve growth factor (NGF) has emerged in recent years as a key driver of peripheral sensitisation in a variety of chronic musculoskeletal conditions. Significant and clinically important pain reduction in placebo-controlled trials of blocking antibodies directed at

NGF strongly implicates this pathway in chronic low back pain, and raises hope of novel pharmacological treatments in the future (Gimbel et al., 2014).

3.2 Central sensitisation

For several decades, central sensitisation and altered central pain processing have been suggested as a unifying underlying mechanism responsible for symptoms in patients with different pain conditions—particularly, chronic LBP. In this hypothesis, enhanced pain transmission leads to a chronic state of pain in the absence of peripheral tissue injury after an initial noxious stimulus. Several mechanisms have been proposed, demonstrating participation in this increased response to peripheral stimulation affecting both the ascending and descending pain pathway. Electrophysiological constructs underpinning the ‘gate control theory’ of pain, and ‘wind-up’ parallel clinical constructs whereby barriers to afferent signals might be deficient in the central nervous system, and repetitive stimulation might lead successive stimuli to cause increased pain (temporal summation). Inadequate descending inhibitory pathways, or augmented facilitation from the brainstem might lead to the same effect. Shared pathways within the brain might link cognitive and emotional processing to pain, such that emotional components are not only essential to the definition of pain, but adverse emotional factors increase pain’s sensory component and vice versa.

The relative contributions of peripheral (in the spine or peripheral nerves) or central (spinal cord or brain) mechanisms to chronic LBP remains difficult to establish, both in populations and individuals (Roussel et al, 2013*). Widespread reduced pain thresholds, suggestive of central sensitisation overlap substantially with non-pain populations and evidence from more objective indices such as spinal RIII reflexes (RIII) have been inconclusive. However, increasing evidence suggests an alteration of brain structure, brain function and brain chemistry in chronic LBP. In comparison with pain-free controls, subjects with chronic LBP have reductions in cortical grey matter in the bilateral dorsolateral prefrontal cortex, thalamus, brainstem, primary somatosensory cortex (S1) and posterior parietal cortex. Reductions in grey matter have been reported in areas associated with inhibitory pain control. Neuroimaging using functional MRI studies provides supportive evidence for augmented central pain processing in these patients, with enhanced activity in the right insula, posterior cingulate cortices and supplementary motor area. A lack of activation of the sensory modulation system was seen in patients with chronic LBP who displayed a high degree of fear-avoidance behavioural changes. Interestingly, these cortical or subcortical changes (in the volume of grey matter and functional activity) have been shown to be reversible (neuroplasticity) and to normalise with successful treatment. It remains unclear, therefore, to what extent these changes might cause rather than merely result from (or reflect) chronic LBP.

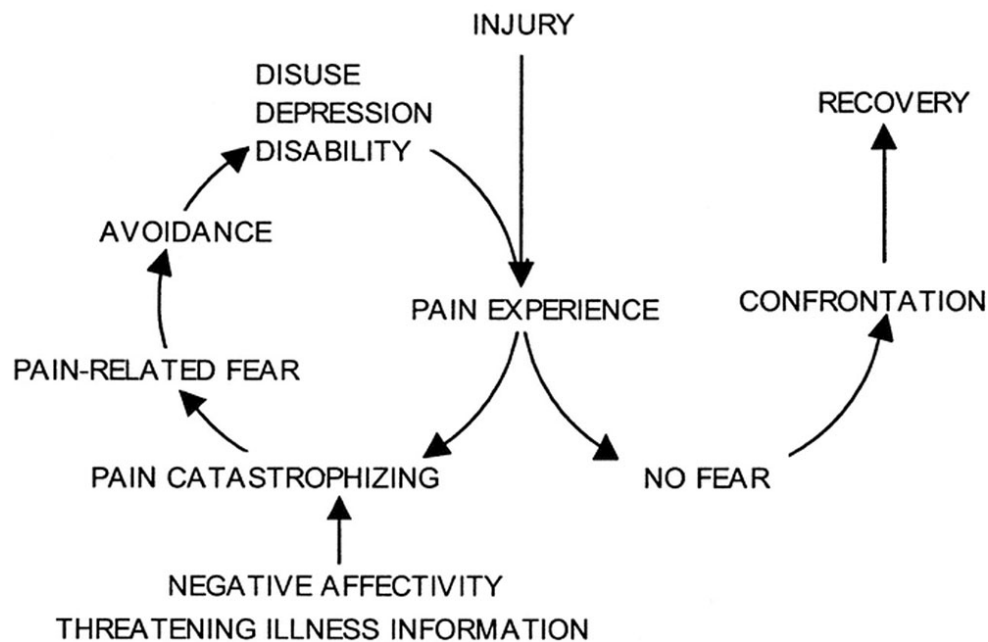

3.2 The biopsychosocial model

In 1987, Gordon Waddell, a Scottish orthopaedic surgeon, published a seminal article in the journal *Spine* (Waddell, 1987). After analysing the epidemiological evidence, he pointed out that the traditional biomedical model alone failed to explain the sharp increase in costs occurred during the past 10–20 years. He argued that a biopsychosocial perspective was more appropriate to understanding this condition because for many people the problem was not the pain itself, which is often transient, but rather their own and society's perceptions and reactions to pain. He then compared rest and active rehabilitation for LBP. Although rest was commonly prescribed, it was based on a doubtful rationale and little or no evidence of a lasting benefit, whereas harm could be expected from prolonged bed rest. By contrast, clinical studies confirming the benefit of active rehabilitation were already available. Unhelpful reactions to LBP include unnecessary avoidance of physical activity and social interaction, resulting in increased absenteeism from work and increased healthcare use. He concluded by advocating a change from the negative philosophy of rest for pain to a more active restoration of function.

Thanks to this model, many studies have confirmed that pre-existing psychological constructs (eg, depression, anxiety, fear-avoidance beliefs) are predictive of poorer outcome, as measured by pain and disability, and that these same constructs are major determinants for the transition from an acute to chronic pain state. Social and organisational factors influence the consequences of back pain, such as work absenteeism. Almost a decade later, new conceptualisations of the relationship between cognitive-behavioural factors, such as pain-related fear and avoidance and disability, and their respective role in the development of chronic pain have been developed (Vlaeyen et al, 1995). The cyclical process whereby pain produces fear, which leads in turn to behavioural avoidance, inactivity, disability and increased focus on pain avoidance, is well described in Vlaeyen's model of chronic pain pathogenesis (figure 2).

In the following years, the concepts of catastrophising (an exaggerated negative orientation towards noxious stimuli) and fear of pain and movement (also called kinesiophobia) have been largely confirmed as central to understanding why patients develop chronic LBP (Wideman and Sullivan, 2011; Parr et al, 2012; Wertli et al, 2014a; Wertli et al, 2014b). However, the description of a linear succession of events starting with pain catastrophising as the cognitive antecedent of pain-related fear, and pain-related fear as the emotional antecedent of depression and disability, may not be as simple as shown in the above model (Corbière et al, 2011). More recent studies seem to indicate that there are two parallel pathways (with some interconnections). On the one hand, there is a unique relationship between depression, pain catastrophising and long-term pain intensity and, on the other, self-efficacy (the beliefs a person holds about his or her power to affect situations), which is related to fear of movement, with both acting on long-term work disability.

Picture 2. Vlaeyen's cognitive-behavioural model of chronic pain pathogenesis. (Reproduced with permission from Vlaeyen et al, Pain 1995;62:363–72.)

Overall, there is no doubt that all these psychological dimensions are extremely important in patients with LBP. There is a large consensus that they should always be explored (see section 4.1.1.2) and present important targets for preventative measures in people with acute or subacute LBP, and for treatment in those with chronic pain (see section 5). Hence, the development of the biopsychosocial model is often reported as a turning point or even a revolution in the world of back pain. Despite this, there was a 45% increase of disability due to musculoskeletal problems between 1990 and 2010, with LBP accounting for nearly half of this figure (Driscoll et al, 2014). LBP is now a worldwide health problem affecting more than 600 million people and one of the leading causes of disability. This negative picture may reflect slowness in scientific, healthcare and occupational communities to adopt the model, rather than being a failure of the model itself.

4 Evaluation

Most guidelines recommend a triage approach for distinguishing between non-specific LBP, radicular syndromes and specific LBP cases after having ruled out vascular, abdominal or other non-musculoskeletal causes. For all patients with acute LBP, a thorough history and brief clinical examination are sufficient. The initial examination has two main purposes: first, to exclude an alternative diagnosis (hip pain, greater trochanteric pain syndrome, sacroiliitis); second, to attempt to identify any 'red flags' that may suggest a specific spinal diagnosis (van Tulder et al, 2006). Red flags are risk factors detected in the past medical history and symptoms of a patient with LBP and associated with a higher risk of a specific cause of LBP (box 1). Broadly, red flags might be classified as 'surgical' or 'medical'. Characteristics suggesting cauda equine compression (bilateral leg pain, bladder or bowel dysfunction, loss of perineal sensation or anal tone) require immediate action due to the potential for long term neurological deficit following delayed decompression.

Medical red flags merit urgent investigation to ensure appropriate treatment, but do not preclude concurrent symptomatic treatment.

Individual red flags do not necessarily link to a specific pathology, but they indicate a higher probability of a medically serious underlying condition. Multiple red flags need further investigation. In the absence of any red flags, no imaging or blood test should be performed. The validity and usefulness of red flag items have been questioned, due mainly to low specificity for treatable specific pathology. Owing to the low incidence of serious life-threatening diseases among patients with LBP, the presence of one red flag should not be over interpreted as being synonymous with infection, malignancy or fracture. Over-investigation of each benign episode of LBP imposes financial burden on health care systems, and might perpetuate diagnostic uncertainty and unhelpful healthcare-seeking behaviours. Reassurance is not necessarily reassuring because no investigation has 100% sensitivity. Repeated episodes of LBP frequently feel different to previous ones. Repeated testing might only reinforce beliefs that the initial tests might have missed something important, and, when negative, might only encourage the patient to seek a third opinion rather than accepting treatment for their problem.

Box 1: Red flag list

Age of onset <20 years or > 55 years
Recent history of trauma
Constant progressive, non-mechanical pain (no relief with bed rest)
Thoracic pain
Past medical history of malignant tumour
Prolonged use of corticosteroids
Drug abuse, immune suppression, HIV
Fever
Systemically unwell
Unexplained weight loss
Widespread neurological syndrome (including <i>cauda equina</i> syndrome)

4.1 Clinical evaluation

4.1.1 Key points from the patient history

During the first consultation with a patient with LBP, with or without leg pain, the physician has to rule out visceral disorders (abdominal, genitourinary, vascular, etc) as the main cause of symptoms or as a comorbidity, and consider several other musculoskeletal causes of pain before focusing specifically on back pain. The topography, characteristics, mode of onset, factors that increase or decrease the intensity of pain, functional

limitations and the results of previous treatments for the same kind of pain, form some of the information to be gathered to establish a diagnosis and develop a management plan.

4.1.1.1 Pain characteristics

These are frequently said to be key elements of the history and patients are often keen to describe their pain in detail. These characteristics might enable some classification into nociceptive pain, neuropathic pain and pain from central sensitisation, hence guiding future treatment (table 1) (Smart et al, 2012a; Smart et al, 2012b; Smart et al, 2012c). Current or previous pain at sites other than the low back, and other 'central' symptoms such as fatigue and psychological distress, might also suggest central sensitisation, but do not exclude local pathology in the spine. People with chronic LBP frequently satisfy classification criteria for fibromyalgia, although it is unclear whether fibromyalgia results as central consequence of chronic focal pain, or should be seen as a comorbidity which exacerbates the problem of LBP.

Table 1: Main characteristics related to three different types of back pain

Nociceptive pain	Neuropathic pain	Central sensitization pain
Pain localized in the area of injury/dysfunction.	Pain referred in a dermatomal or cutaneous distribution.	Disproportionate, non-mechanical, unpredictable pattern of pain provocation in response to multiple/non-specific aggravating/easing factors.
Clear, proportionate mechanical/anatomical nature to aggravating and easing factors.	History of nerve injury, pathology or mechanical compromise.	Pain disproportionate to the nature and extent of injury or pathology.
Usually intermittent and sharp with movement/mechanical provocation; may be a more constant dull ache or throb at rest.	Pain/symptom provocation with mechanical/movement tests (e.g., active/passive, neurodynamic) that move/load/compress neural tissue.	Strong association with maladaptive psychosocial factors (e.g., negative emotions, poor self-efficacy, maladaptive beliefs, and pain behaviour) and diffuse/non-anatomic areas of pain/tenderness on palpation.
Absence of pain in association with other dysesthesias, night pain/disturbed sleep, antalgic postures/movement patterns and pain variously described as burning, shooting, sharp or electric shock-like.		

4.1.1.2 Risk factors for chronicity (yellow flags and other flags)

Understanding the course of back pain from acute or recurrent to chronic is of paramount importance when treating people with LBP. On the one hand, most acute episodes will resolve spontaneously even without treatment but, on the other hand, chronic disabling back pain is one of the greatest health problems we are facing today. Investigating and modifying risk factors for chronic disabling LBP early in the course of an episode is a key task for clinicians. Once thought to be important, physical and radiological factors have been

repeatedly shown to have limited influence on chronicity, whereas major determinants of chronicity are psychological and social factors (Main et al, 2008). Following the idea of red flags as signals for specific back pain, these psychological and social factors have been recorded under several coloured flags. Yellow flags designate psychosocial barriers to recovery, whereas orange flags designate psychiatric comorbidities (eg, substance abuse, personality disorder, anxiety, etc). Blue flags refer to conditions in the workplace that may inhibit recovery, such as monotony, low degree of control, poor relationships or high work demands. Finally, organisational issues, such as financial reliance on disability benefits, workers' compensation problems or employer attitudes are examples of black flags. Table 2 summarises the strength of evidence and the predictive strength of the principal variables according to Main et al.

Table 2: Main factors for low back pain (LBP) chronicity

Variable	Strength of evidence [†]	Predictive strength [‡]	Flag assignment
Clinical history (LBP)	***	***	Red/yellow
Poor perceptions of general health	***	**	Yellow
Psychological distress	***	***	Yellow/orange
Depression	***	**	Orange/yellow
Fear avoidance	**	**	Yellow
Catastrophizing	***	**	Yellow
Pain behaviour	***	**	Yellow
Duration sickness absence	***	***	Yellow/blue/black
Employment status	***	***	Blue/black
Job dissatisfaction	***	***	Blue
Expectations for return to work	***	***	Blue
Physical demands of work	***	*	Black
Financial incentives	***	***	Black
Unemployment rates	**	***	Black

[†]Strength of the evidence: ***strong evidence: generally consistent findings in multiple, high-quality, scientific studies; **moderate evidence: generally consistent findings in fewer, smaller or lower-quality scientific studies; *weak, limited or conflicting evidence: one scientific study or inconsistent findings in multiple scientific studies.

[‡]Strength of the effect (the power of the predictor): ***strong predictor; **moderate predictor; *weak predictor.

Most of these factors have a direct impact on work status. Early in the course of chronicity, expectation of returning to work within the following months is an additional important measure since the longer the length of absence from work due to LBP, the lower the chances of ever returning to work. After more than 6 months' absence, the chances of returning to work are low, whatever treatment is given.

4.1.2 Key points from physical examination

Although the scientific validity of many clinical variables that contribute to the physical examination leading to diagnosis and treatment is limited, it is important to recall that patients consider history taking and a physical

examination part of a good 'back consultation'. Perhaps even more important to patients is communication and feedback (Laerum et al, 2006*). Information should be given in everyday language, consecutively and consistently during the clinical assessment and when evaluating imaging.

A brief physical examination is always an essential part of the assessment of acute LBP. Hip and sacroiliac pathologies must be excluded as both can mimic non-specific LBP. The passive straight leg raising (SLR) test is key to identifying lumbar radiculopathy due to disc herniation (figure 3). Although there is limited information in the primary care population, studies performed in patients requiring surgery show that a properly conducted SLR test (Lasègue test) is the most accurate for identifying nerve root pain. The SLR test has high sensitivity, while the crossed SLR test has high specificity. However, a review from the Cochrane Collaboration concluded that most physical tests have a poor performance when used in isolation (van der Windt et al, 2010) and it is a combination of tests that helps the clinician to make the diagnosis.

Picture 3: Passive straight leg raising test

The SLR test requires a firm level couch, with a supine, relaxed patient with trunk and hips without lateral flexion. The practitioner should ensure that the patient's knee remains extended, with the foot in the vertical

plane. The affected leg is supported at the heel and the limb gently raised (figure 3A). The angle of elevation at the onset of pain and the site of pain is recorded. The SLR test is positive if typical leg pain is reproduced. False positives due to pain on hip flexion should be excluded through hip examination. Neurological signs (myotomal or dermatomal motor or sensory deficits or reduced knee or ankle reflexes) might increase specificity, but even substantial nerve root compression can occur in the absence of reflex changes due to innervation through multiple nerve roots. Several additional techniques to increase sensitivity have been described but not validated: (a) the ankle dorsiflexed (figure 3B); (b) the hip medially rotated (figure 3C) and (c) the neck flexed (figure 3D). Reproduction of symptoms by one of these tests would be interpreted as a positive passive SLR outcome, suggesting increased root tension.

In addition to history taking and a passive SLR test, spinal palpation and motion tests are often used to verify the presence of muscle spasm, sub classify LBP mechanisms and/or to evaluate the effectiveness of an intervention. Specificity and sensitivity of these clinical tests have been difficult to determine in the absence of gold standards and incomplete benefit from specific treatments, although inclusion in the clinical examination might be important in providing a rational context for treatments which might be offered. Tenderness, unilaterally or bilaterally, on lumbar para-spinal palpation, plus increased LBP on extension (more than flexion), rotation, or combined extension/side or extension/rotation, might suggest pain originating from facet joints (Mars et al., 2015).

4.2 Subgroup classification

Heterogeneity amongst people with LBP might limit the apparent effectiveness of any single treatment in randomised trials, and provides a rationale for stratified or personalised care. Stratified care requires the identification of homogeneous subgroups of people with LBP in whom a specific treatment is likely to be effective. Personalised care requires customisation of treatment packages to the particular problems and needs displayed by the individual. Stratification based on underlying pain mechanisms remains the cornerstone of the scientific practice of medicine, but has been problematic due to the often multiple and overlapping pain mechanisms that might contribute to LBP and the uncertainty that surrounds identifying specific mechanisms in each individual. Stratification based on prognosis has benefits of empirical evidence for cost-effectiveness (*Hill et al., 2011). Groups of patients destined to do badly are likely to gain most benefit from treatment, and where poor prognosis is attributable to adverse risk factors, modifying those risk factors is most likely to be effective. One review identified 16 different diagnostic classification systems, seven prognostic systems and five treatment-based systems (Fairbank et al, 2011).

Imaging contributes little information on prognosis, and should only be used to identify specific mechanisms for which treatments might be effective, or to exclude pathologies that might pose unnecessary risk to the delivery of a treatment. Spinal surgery modifies spinal structure, and structural imaging is an appropriate

prerequisite for surgery. However, treatments offered by most primary care physicians, chiropractors, physical therapists, physiotherapists, rheumatologists, etc have effects which seem to depend little, if at all, on findings from spinal imaging (McCarthy et al, 2012; Wang et al, 2012; Widerström et al, 2012; Billis et al, 2013; Hall, 2014). A common perception that imaging is required to ‘see the cause of the pain’ before treatment can be planned is unjustified by evidence, can delay effective treatment (for example avoiding exercise until a scan has ‘shown it to be safe’), and can increase healthcare costs. Even in acute sciatica, imaging evidence of nerve root compression only weakly predicts outcome from epidural steroid injection (Ekedahl et al., 2017), although precise localisation of pathology might be important to ensure appropriate location of transforaminal injection.

The STarTBack screening tool is designed to be used by primary care physicians or therapists at the first point of contact for an episode of LBP, and has the best validation process, including randomised clinical trials and large, ‘real-life’, cohort studies (*Hill et al., 2011). It was developed as a ‘prognostic’ system, and focused on modifiable risk factors which inform treatments offered to high risk subgroups. It contains nine items: four deal with the pattern of pain and disability, four cover potentially modifiable psychological aspects (kinesiophobia, anxiety, depression, and catastrophism) and one scores the level of bothersomeness. The tool can be used to stratify patients into 3 groups with low, medium or high risk of chronicity. Providing early intensive treatment, incorporating both physiotherapeutic and psychological interventions, to the highest risk group improved outcomes, while limiting treatment to advice alone for those with good prognosis reduced healthcare costs (*Hill et al, 2011). STarTBack effectively stratified people with LBP with or without sciatica. People who have already failed first line treatments, however, have already identified themselves as being in a poor prognosis group, and STarTBack might have less utility as a stratification tool in secondary care settings.

4.3 Questionnaires, patient-reported outcomes

Patient-reported outcomes are data collected by self-administered questionnaires. Although they have been criticised for their lack of objectivity, they have shown a better correlation with clinical outcomes in patients with LBP than the results of physical examinations and imaging studies. This may be because pain is, by definition, an individual experience that cannot be objectively revealed. Moreover, patients’ self-perception is an important driver in their decision to seek or act on medical advice and, consequently, in costs generated. Once used mainly in clinical trials, these questionnaires are now advocated for use in the clinical setting. Given the multidimensional nature of pain, no single outcome measure is sufficient. Several validated tools exist, and the most popular have been cross-culturally adapted to several languages (table 3).

Table 3: The most frequent patient-reported outcomes in low back pain

Dimension	Examples of patient-reported outcomes
Pain	Visual analogue scale Numeric rating scale
Back-specific function	Oswestry Disability Index Roland and Morris Disability Questionnaire
Kinesiophobia	Tampa Scale Fear-Avoidance Belief Questionnaire
Anxiety and depression	Hospital Anxiety and Depression Scale Beck Depression Inventory
General health	Short Form Health Survey (SF-36, SF-12) Euroqol-5 Dimensions
Multidimensional	Core Outcome Measures Index Dallas Pain Questionnaire

The Core Outcome Measures Index, a brief multidimensional questionnaire, has been developed and validated in several languages (Mannion et al, 2005). This tool includes a series of questions about the domains of pain (back and leg/buttock pain intensity), each measured separately on a 0–10 numerical graphic rating scale, including function, symptom-specific well-being, general quality of life and social and work disability (each on a five-point Likert scale). It has gained wide acceptance and is at the centre of the evaluation forms used by the European Spine Registry (also known as Spine Tango).

4.4 Imaging in LBP

Diagnostic imaging tests (including X-ray examinations, CT and MRI) are not routinely indicated for LBP. They serve one major purpose: to identify specific pathology for which treatment would be considered (e.g. surgery for cauda equina or radicular pain, radiotherapy for metastatic cancer, medical treatments for ankylosing spondylitis). Imaging should be reserved for patients who are considering surgery or those in whom a serious disease (based on red flags) or radicular syndrome is strongly suspected. Patients might have high expectations that imaging will be instigated by the clinician, but inappropriate imaging in patients with LBP has several major drawbacks without improving outcome (Chou et al, 2009). Inappropriate imaging increases costs for society and might cause iatrogenic harm, leading to worse scores on back-specific functional and generic health-related quality of life questionnaires (Graves et al, 2012; Graves et al, 2014; Webster et al, 2014). Patient and public expectations from spinal imaging should be carefully managed both in the clinic and in society, in order to help optimise risks and benefits.

4.4.1 Plain radiography

The anteroposterior and lateral views demonstrate the general anatomy of the spine and allow a gross assessment of bone density and architecture, including the presence or absence of lumbosacral transitional

alignment and disc and vertebral body height. However, soft tissue structures are not properly evaluated by radiography. Oblique views show the pars interarticularis in profile and are useful for diagnosing spondylolysis when this is suspected. Other special views include flexion and extension views to assess instability, and an angled view of the sacrum to assess sacroiliac joints for ankylosing spondylitis.

4.4.2 Computed tomography

CT uses X-rays to generate cross-sectional images of the spine. Although spinal images can be obtained only in the frontal or slightly off-frontal plane, sagittal and coronal reconstruction can be produced. CT can accurately depict the foraminal and extraforaminal nerve root because surrounding fat provides natural contrast.

4.4.3 Magnetic resonance imaging

MRI has several advantages over CT for spinal imaging, including both visualisation of soft tissues and absent radiation risk, but claustrophobia can be problematic, as can be contraindications such as metallic implants. Different parts of the disc (nucleus pulposus and annulus fibrosus) can be distinguished from one another; ligaments can also be visualised. MRI offers better visualisation of the vertebral marrow and the contents of the spinal canal. A disadvantage of MRI is that it cannot be used to visualise cortical bone directly. In 1988, Michael T Modic, professor of radiology and neurology at Case Western University, Cleveland, USA, proposed a classification of MRI changes linked to disc disease and his name has been associated with these changes ever since. The 3 types of Modic changes, common observations in MRI (Takatalo et al, 2012), refer to signal intensity changes in endplates of affected discs (table 4). Type I represents oedema and the presence of an inflammatory reaction has been reported (figure 4A). Histological examination shows disruption and fissuring of the endplate and vascularised fibrous tissues within the adjacent marrow. Type II is the most common type of change, representing fatty degeneration of subchondral marrow (figure 4B). Histological examination shows endplate disruption with yellow marrow replacement in the adjacent vertebral body. Type III correlates with extensive bony sclerosis on plain radiographs (figure 4C). Histological examination shows dense woven bone and, thus, no marrow to produce a MRI signal. Progression from type I to type II has been frequently reported (as well as a mixed type combining types I and II) and may take several years. Changes from types I or II to type 0 (normal) or from type 0 to type II are also common.

Table 4: The three main forms of Modic changes

Type	T1	T2	Significance
I (Picture 4A)	↓	↑	Oedema Inflammatory reaction
II (Picture 4B)	↑	→ (or slight ↑)	Fatty degeneration
III (Picture 4C)	↓	↓	Bony sclerosis

Picture 4: The 3 main forms of Modic changes

Picture 4A: MODIC 1, discopathy L5-S1

Picture 4B: MODIC 2, discopathy L2-L3

Picture 4C: MODIC 3, discopathy L4-L5

5 Treatment

It is important to recall that only a minority of patients with non-specific LBP seek medical attention. An economic study including a random sample of some 38 000 people with LBP showed that different clusters of healthcare system users can be identified. The vast majority ($n = 35\,675$) remain 'low users' with three other subgroups that changed from 'high' to 'low' care use ($n = 1272$), or from 'low' to 'high' ($n = 807$) and, finally, a small group ($n = 237$) that remained 'high' users of the healthcare system over the 2 years of the study (Ruetsch et al, 2013).

5.1 Guidelines

Over the past 15 years, many guidelines from different countries or societies have been published. Overall, there are few differences, except for some adaptations related to increased knowledge in some areas. Importantly, it has been shown repeatedly that compliance with guideline recommendations—by refraining from early imaging and other aspects of patient management—significantly reduces costs (Graves et al, 2014; Webster et al, 2014). Guidelines consistently recommend patient education and physical activity, advise against shoe insoles or orthoses and lumbar supports. Recommendations for or against spinal manipulation or mobilisation are less consistent. Differences between guidelines might in part reflect different perspectives and purposes. For example, the UK National Institute for Health and Care Excellence (NICE) adopted a health economic perspective (*Ward et al., 2016), which excluded costs to employers and social care. Health care costs, and the thresholds at which benefits might be considered value for money might vary between countries. Not all interventions are equally tested through randomised controlled trials, leaving scope for variation in expert opinions between guideline development groups.

The full NICE guidance (NICE CG173) lists 41 recommendations, plus additional links to other relevant guidance for the medical management of neuropathic pain (*Ward et al., 2016). Positive guidance recommends consider stratification (e.g. STarT Back at first point of contact), provide information and encouragement to continue normal activities and return to work, and consider a group exercise programme. Analgesic approaches should consider non-steroidal anti-inflammatory drugs or, if contraindicated, weak opioids with or without paracetamol. Combined physical and psychological programmes should be considered for people with persistent symptoms or earlier if there are adverse risk factors.

Qualified recommendations for manual or psychological therapies indicate that they should only be offered as part of treatment packages that include exercise. Paracetamol should not be offered alone, and opioids not routinely for acute LBP nor at all for chronic LBP. Important negative recommendations are to not offer foot orthoses, rocker sole shoes, belts or corsets, traction, acupuncture, ultrasound, percutaneous or transcutaneous electrical nerves stimulation, nor interferential therapy. NICE recommended that antidepressants, anticonvulsants or spinal injections should not be offered for LBP (as opposed to sciatica).

5.2 Additional comments

Previously mentioned treatments represent only a minority of even the 200 that were cited in a non-exhaustive review published in 2008. Although at times frequently prescribed, most have not been validated. It is important also to recall that the mean clinical benefit above placebo effects of most treatments reporting efficacy is small (about 10–15 points on a 0–100 scale for pain intensity reduction).

5.2.1 Information and advice

Great emphasis has been placed on information and reassurance, especially for acute and subacute LBP. Information can contribute to iatrogenic disability when it is based on pathological diagnosis for a work-related injury, a description of the anatomy and biomechanics of the spine, activity restriction or modification, and ergonomic advice (van Tulder et al, 2006). By contrast, advice to stay active and to continue ordinary activities as normally as possible, with an emphasis on advantageous coping strategies rather than being an ‘avoider’, produce a faster recovery, faster return to work and less disability. It has been shown also that physicians believing in the biomedical model of injury—rather than the biopsychosocial model—can have a negative impact on the future of their patients if they prescribe more bed rest and longer sick leave.

5.2.4 Spine surgery

Retrospective data from the USA between the mid-1990s and the first decade of this century showed a dramatic multiplication in the use of imaging, opiates and spinal injections, and also of the number of surgical procedures. These procedures are mainly spinal fusions, with a four- to fivefold increase over the past 15 years but without any clear benefit for patients. According to most guidelines, the role of surgery for LBP is very

limited. The rationale for surgery is weak as the demonstration of segmental instability (which might justify a segmental fusion) remains unclear.

Systematic reviews have shown that the results of surgery are comparable to those of structured multidisciplinary programmes (cognitive behavioural therapy and exercise rehabilitation) (Bydon et al, 2014). Long-term follow-up (9 and 11 years, respectively) have shown no differences in outcome between the surgical and the conservative arms in controlled trials. Moreover, there are no valid criteria for the selection of candidates who are most suitable for surgery. However, a pooled analysis of three randomised clinical trials showed that one-quarter of patients were able to stop analgesic treatment in the long term (Mannion et al, 2013*). Randomised controlled trials might be subject to selection biases (for example if participants were only recruited if their perceived need for surgery were in doubt), and it remains possible that there is a subgroup of patients with severe chronic LBP who might benefit from surgery. However, further research would be needed to enable any such responsive subgroups to be identified and to further justify the risks of surgery in clinical practice.

6 LBP entities possibly related to specific radiological findings

6.1 LBP in the adolescent

In past decades, the most prevalent theory for juvenile LBP could be summarised as almost the denial of the existence of non-specific pain. The corollary was aggressive investigations to rule out serious or even life-threatening diseases in these cases. There is now sufficient evidence to show that the most common diagnosis among adolescents with LBP is non-specific LBP, even though the probability of identifying a specific lesion (mainly spondylolysis or spondylolisthesis) is higher than among adults.

This section summarises some basic information about three spinal disorders often seen in adolescents

6.1.1 Spondylolysis/spondylolisthesis

Spondylolisthesis was described as early as 1782 by Dr Herbinaux, a Belgian obstetrician. Despite its long history and its prevalence (about 6% of the population), our understanding of the condition is still incomplete. It is generally admitted that spondylolysis or spondylolisthesis are not present at birth and probably appear when children can stand. L5 vertebrae are involved in the vast majority of cases. Familial clustering was identified by the first epidemiological studies more than 50 years ago. The main mechanism of injury (ie, lysis) of the pars interarticularis is usually a combination of repetitive flexion, extension or rotation of the lumbar spine. Acute traumatic injury is rare. An increased prevalence is found among adolescents with a high level of sporting activities (eg, gymnasts). In most series, there is a clear male predominance.

A study with a 45-year follow-up showed that spondylolisthesis appears in two-thirds of patients with spondylolysis, but none of these patients ended up with a slip of >39% (grade II) (Beutler et al, 2003). Severe

slips are uncommon, but do exist. These cases (grades III and IV) show more frequent symptoms, including neurological findings. Some predictors of high-grade slip have been identified: female sex; dysplastic slip; presence of a grade II spondylolisthesis during growth years; a high slip angle (kyphosis at the spondylolisthesis level); a familial history of higher grade spondylolisthesis and presence of hyperlaxity or connective tissue disorder. Many individuals are asymptomatic. Clinical signs may include altered gait, limited forward flexion, a palpable step-off of spinous processes and hamstring tightness (figures 5 and 6).

Picture 5. L5-S1 bilateral spondylolysis with grade I spondylolisthesis in a 16-year-old girl

Picture 6. The four grades of spondylolisthesis. The grading from I to IV is obtained by dividing the sacral plateau of S1 into four equal parts. A fifth stage, spondyloptosis is an uncommon finding. The image shows a grade I spondylolisthesis associated with spondylolysis.

Modern imaging studies can identify pre-lytic stages of spondylolysis. Different studies have shown that hyperflexion and hyperextension radiographs are not helpful as many patients have hypomobile segments. For safety and economic reasons, routine dynamic radiographs should not be obtained for adolescents. Conservative management includes bracing, which leads to excellent lesion healing when diagnosed at a pre-lytic stage (bone oedema) or at the beginning of the fracture, but clearly before the two bony extremities exhibit cortical bone. Surgery is recommended for patients with progressive high grades.

6.1.2 Scheuermann's disease

Scheuermann's disease is usually defined as a focal developmental kyphosis, but the causes are still not understood, although it was recognised more than 100 years ago. The main characteristics include an irregularity of the endplates of the vertebrae, sometimes with Schmorl's nodes and/or other vertical (ie, intracorporeal) disc herniations, disc narrowing and wedging of the vertebral bodies. For diagnosis, involvement of one vertebral body is sufficient for some authors, whereas others require at least three consecutive vertebrae. Wedging $\geq 5^\circ$ in three consecutive vertebral bodies is one of the usual criteria. Some consider that the thoracic kyphosis should be greater than 35° or 45° .

The diagnosis is frequently made around the time of puberty. Pain is often reported, but not always, and the functional capacity is usually good. Pulmonary function is not reduced unless the kyphosis exceeds 100° . A neurological examination is usually normal and hamstring tightness is often seen. The differential diagnosis includes compression fractures, spondyloepiphyseal dysplasia tarda, osteogenesis imperfecta (type I), neurofibromatosis and connective tissue disorders (eg, Marfan, Ehlers–Danlos). Conservative management relies on physical therapy and bracing. Physical therapy may alleviate pain, but has no effect on deformity. Bracing can improve the angle of kyphosis in patients with significant growth remaining. Severe deformities may require surgery.

6.1.3 Adolescent idiopathic scoliosis

By definition, this section excludes scoliosis that appears earlier in life (ie, congenital, infantile and juvenile scoliosis), and those types with a clearly identified aetiology. These are dealt with by specialised paediatric orthopaedic surgeons and rarely managed by rheumatologists (Sponseller et al, 2012).

The usually accepted definition of adolescent idiopathic scoliosis is that of a scoliosis of unknown cause with a Cobb angle $>10^\circ$ beginning after the age of 10 years (box 2) (Weinstein et al, 2008b; Makurthou et al, 2013). The aetiology remains unclear, although it is generally accepted that this is a multifactorial disease with genetic predisposing factors (table 5) (Altaf et al, 2013). Adolescent idiopathic scoliosis is neither associated with a decreased life expectancy nor should it be the origin of major pain. The major problems are cosmetic

and psychosocial, related to the progression of the curve, respiratory (not comparable with the dramatic consequences of scoliosis due to poliomyelitis) and, to some extent, pain.

Box 2 Classification of scoliosis

1. Congenital (associated with segmentation or formation defects)
2. Syndromic
2.1 Neuromuscular
2.2 Associated with neurofibromatosis or connective tissue diseases (Marfan's disease, Ehlers-Danlos)
3. Idiopathic (subdivided by age of diagnosis into the following categories)
3.1 infantile (from birth up to 3 years of age)
3.2 juvenile (from 3 to 10 years of age)
3.3 adolescent (from 10 years to skeletal maturity) that can be classified topographically according to Lenke into the following six main categories:
1. Main thoracic
2. Double thoracic
3. Double major
4. Triple major
5. Thoracolumbar/lumbar
6. Thoracolumbar/lumbar/main thoracic
3.4 adult

Table 5 Main pathogenic hypotheses underlying idiopathic scoliosis (Reproduced with permission from Altaf et al, BMJ 2013;346:f2508)

Intrinsic factors	Extrinsic factors
1. Genetics (well described; different inheritance modes; numerous candidate regions/genes have been suggested)	1. Left-right asymmetry (<u>not</u> handedness)
2. Growth and development of the spine (altered growth of the vertebral bodies and posterior elements; no evidence of a causative role)	2. Nervous system (decreased sensory input, dysfunctions at different sites, uncoupled neuro-osseous growth, etc.; role unclear in idiopathic scoliosis)
3. Intervertebral disc development asymmetry	3. Paravertebral muscle weakness
4. Spinal ligaments: no evidence in humans	4. Ribs (role unclear in idiopathic scoliosis)
5. Mechanics of the upright spine (type of rotatory instability of the immature spine).	5. Osteoporosis/low bone mineral density
	6. Increased platelet calmodulin levels (role unclear in idiopathic scoliosis)
	7. Melatonin (role unclear in idiopathic scoliosis)

**Some of the factors are based on animal models of scoliosis, consequences of surgical procedures, diseases, etc.*

The most relevant aspects for a clinician who does not specialise in deformity are the ability to identify the main prognostic factors and atypical elements requiring referral and/or MRI studies. A full history and clinical

examination, including three-planar spinal posture from the back and the side, is important and should encompass at least the elements listed in table 6 (Hresko, 2013).

Table 6 Key points from history and physical examination in idiopathic scoliosis (Reproduced with permission from Hresko, *N Engl J Med* 2013;368:834–41)

History	Full physical examination (from the back, side, and front)
Birth history	Gait
Developmental milestones	Skin inspection (signs of neurofibromatosis, dysgraphia signs, etc.)
Familial history of spinal deformity	Spinal balance with plumb line
Physiological maturity (growth spurt and menarchal status)	Shoulder and iliac crest elevation
Past medical and surgical history (elements that correlate to a syndrome or congenital condition)	Flank asymmetry
Pain history (nocturnal? constant? associated symptoms or signs?)	Adams forward bent test (at different levels)
Evolution of the deformity (rapid progression suggest a non-idiopathic aetiology)	Sagittal plane balance
Neurologic symptoms (weakness, sensory changes, gait problems, bowel or bladder control changes, etc.)	Anterior thoracic wall
	Full neurologic examination
	Joints range of motion, laxity, deformity, etc.
	Hyper laxity criteria
	Pubertal stages (auto-evaluation forms have been used with different accuracy rates)

The main prognostic factors are the maturity (menarchal status and Tanner stages), the magnitude of the scoliosis (Cobb's angle) and the remaining growth (Risser stage). As a general rule, a Cobb angle $>30^\circ$ represents a significantly increased risk of aggravation throughout adult life, whereas curves below that threshold have a very limited risk of progression. Double curves and scoliosis in girls have an increased risk of progression. Some characteristics are reassuring in adolescent scoliosis, thus allowing a rheumatologist with some experience of spinal disorders to take care of these patients. Other characteristics should be considered atypical and require prompt referral to a specialised spine orthopaedic surgeon (table 7).

Table 7 Key elements in the evaluation of adolescent scoliosis

Reassuring elements	Suspicious elements
Right thoracic, right thoracic and/or left lumbar, or left thoracolumbar curve.	Left main thoracic curve
Absence of sagittal imbalance, thoracic hypokyphosis	Hyperkyphosis combined with a thoracic scoliosis (increased risk of associated Arnold-Chiari malformation and syringomyelia).
Curves <20° without sharp angulation	Sharply angulated curves, curves with congenital bony anomalies, and very large curves
Growth spurt finished Sufficient maturity (Tanner stages, menarche, Risser stages)	
Absence of pain	Substantial pain
Normal neurologic examination	Neurologic complaints, bladder problems, neurologic signs e.g., muscle weakness and/or long tract signs
	<i>Pes cavus</i> Severe joint laxity

The evaluation requires full-length standing posteroanterior and lateral radiographs of the spine. For protection from radiation, an EOS system should be used when available. In addition to the list of suspicious elements cited previously, a full MRI study of the spine (from the craniocervical junction to the sacrum) and/or referral to a deformity specialist should be carried out for cases of neurofibromatosis, midline cutaneous abnormalities (associated with neural tube defect) and kyphotic apex of the curve.

The efficacy of bracing has been demonstrated by reviews and randomised clinical trials (Weinstein et al, 2013). It depends on compliance, and wearing a brace for ≥ 13 hours a day has a success rate >90%. For highly compliant patients, the number needed to treat to prevent one operation has been estimated as 4 (95% CI 2 to 7). Evidence also supports specific physiotherapy exercises aiming at autocorrection. In contrast, electrical stimulation has not been shown to be effective, and manipulations or massage have not been evaluated in high quality studies; thus no definite conclusion can be drawn. Surgery can be considered when progressive scoliosis exceeding 45° in an immature skeleton or progressive and/or associated pain occurs after skeletal maturity.

6.2 Inflammatory LBP

Inflammatory back pain is still not perfectly defined (Burgos-Vargas and Braun, 2012; Weisman, 2012). Diagnostic classification of axial spondyloarthritis prior to the emergence of radiographic features is important both in predicting prognosis and offering early and appropriate treatment (Corbett et al., 2016). Different sets

of criteria (mainly classification criteria) with some differences in sensitivity and specificity have been developed in order to identify an increased risk of axial spondyloarthritis (table 8).

Table 8 Comparison of published sets of criteria for inflammatory back pain (Backland et al, 2013; Solmaz et al, 2014)

Criteria	Calin et al	ESSG	Berlin 1	Berlin 2	ASAS
Pain location	Back	Neck/dorsal/back	Low back	Low back	
Age (now)	Any	Any	<50 years	<50 years	
Duration 3 months	✓	✓	✓	✓	
Insidious onset	✓	✓			✓
Age at onset of pain	<40	<45		<30	<40
Morning stiffness >30 min	✓ (duration not specified)	✓ (duration not specified)	✓	✓	
Pain improves with exercise	✓	✓			
Pain improves with activity/not with rest			✓	✓	✓
Pain awakens during 2 nd half of night			✓		✓ (no precise timing + improvement upon getting up)
Alternating buttock pain			✓		

ASAS, Assessment of the Spondyloarthritis International Society; ESSG, European Spondylarthropathy Study Group.

Although the odds for axial spondyloarthritis are tripled when inflammatory LBP is present, an important minority of patients classified as non-specific LBP (up to 25% according to some studies) will present with inflammatory back pain (Hamilton et al, 2014). MRI might reveal pre-radiographic axial spondyloarthropathy, and treatment of severe pre-radiographic disease with TNF-alpha blocking agents has been associated with good results (Corbett et al., 2016).

From the description of the Modic changes in the endplate, clinicians have been most interested in the so-called 'inflammatory changes' or Modic 1 changes, that might occur in people without spondylarthropathy (Kääpä et al, 2012). Although still controversial, there is some evidence that Modic 1 changes are infrequently found in asymptomatic individuals and are indeed associated with an inflammatory pattern of pain, which is

not the case for Modic changes 0, 2 and 3. The size of these lesions shows no direct correlation with clinical symptoms, although the clinical symptoms tend to be fewer when the inflammatory images are of a mixed type (Modic 1 and 2). Patients with Modic 1 changes may also have a worse outcome at 1 year, having greater pain and being less likely to return to work (Keller et al, 2012).

Two Danish articles highlighted the possible involvement of *Propionibacterium acnes* in patients developing Modic 1 in the months after an episode of sciatica due to disc herniation (Albert et al, 2013a; Albert et al, 2013b). The role of infectious agents and the value of antibiotic treatment in this cohort of highly selected patients were widely discussed, with different hypotheses proposed. However, these results remain controversial.

Several studies have suggested that patients with Modic type 1 changes have a better response to NSAIDs and corticotherapy than those with other Modic patterns (0, 2 or 3). Initial reports have described a better outcome after spinal fusion (spondylodesis), but this has not been confirmed.

6.3 Diffuse idiopathic skeletal hyperostosis

Diffuse idiopathic skeletal hyperostosis (DISH) is a systemic non-inflammatory condition characterised by ossification of the enthesis. Although all entheses can be affected, calcification of the anterior longitudinal ligament of the spine is most characteristic (Utsinger et al, 1976). The prevalence and incidence are undetermined, but DISH seems to affect mainly men aged >40 years. Obesity, hypertension, diabetes mellitus, hyperinsulinaemia, dyslipidaemia and hyperuricaemia are metabolic conditions that have all been associated with DISH.

DISH is often asymptomatic. Spinal stiffness is the most common complaint, whereas spinal pain is not usually a major problem, although it is reported by 30–50% of patients (Mata et al, 1997). Extraspinal lesions have been described for most joints but the most problematic is hip involvement, which can sometimes be associated with extensive joint destruction requiring arthroplasty.

The radiological changes are mainly located in the right side of the thoracic spine where the bony appositions tend to form a more or less complete flow of ossification (Resnick and Niwayama, 1976) (figure 7).

Ossification mainly affects the anterior part of the cervical spine and, on a lateral view, these images have been compared with a candle flame. These ossifications can rarely compress the oesophagus, causing dysphagia and disorders of the larynx or pharynx or of the lung. Myelopathy can result from ossification of the posterior ligaments. At the lumbar spine level ossifications are more horizontal, facing each other and forming a 'lobster claw', and are often asymptomatic.

Figure 7 Diffuse idiopathic skeletal hyperostosis. (Source: Cofer, <http://www.lecofer.org>)

The main differential diagnosis is axial spondyloarthritis. The main features for distinguishing DISH from axial spondyloarthritis are the presence of ossification around the sacroiliac joint, the absence of sacroiliitis or extra-articular manifestations and normal acute phase.

Treatment parallels that for non-specific chronic LBP and a better control of associated metabolic disorders is advocated. Surgical procedures are sometimes required in cases of digestive (dyspepsia) or neurological manifestations (radiculopathy or myelopathy).

6.4 Degenerative scoliosis

Degenerative scoliosis is defined as a spinal deformity of $>10^\circ$ (Cobb angle) within the frontal plane in the skeletally mature spine (figure 8).

Figure 8 Degenerative scoliosis in a 71-year-old woman.

Aebi has highlighted three types: (1) primary degenerative de novo scoliosis; (2) progressive idiopathic scoliosis and (3) secondary degenerative scoliosis. The last of these has been further stratified as follows: (a) following idiopathic or other forms of scoliosis as a result of pelvic obliquity, leg length discrepancy, hip pathology or a lumbosacral transitional anomaly; and (b) related to metabolic bone diseases (mostly osteoporosis), leading to asymmetrical osteoarthritic disease and/or vertebral fractures (Aebi, 2005).

The aetiology of primary scoliosis (type 1) remains unclear. However, asymmetrical disc degeneration (discopathy) seems to trigger frontal plane deviation and asymmetrical facet joint loading, leading to rotatory movements of the vertebrae. The latter may result in spinal and foraminal stenosis (more often than in secondary forms). The apex is usually found at L3–L4 or L2–L3 levels with thoracolumbar or lumbar localisation. Instability can lead to ligamentum flavum hypertrophy, facet joint hypertrophy and, therefore, central spinal stenosis. Type 2 is often seen after instrumentation at a young adult age or after conservative treatment of idiopathic scoliosis. Sagittal plane deformity known as ‘flat back syndrome’ or loss of the

physiological lumbar lordosis is found when there are symptoms of pain. The underlying cause of type 3a may be either 'inside' (eg, hemi sacralisation) or 'beyond' the spine itself (pelvis, leg length discrepancy).

Malalignment is mainly seen in the frontal—but not in the sagittal—plane, which thus tends to have no rotatory component. Type 3a is found in the lumbosacral, lumbar or thoracolumbar segments, whereas type 3b can be found along all spinal segments. In the latter case, destruction of discs, facet joints (and capsules) can lead to deformity in the sagittal and frontal planes.

Degenerative scoliosis is rarely seen in people aged <40 years and has a balanced male:female ratio (Grubb et al, 1988*). Curve progression was found to be a Cobb angle increase of 1–3° a year but may be more rapid in the perimenopausal period. The dominating symptom is usually mechanical back pain with muscular overload if unbalanced and neurogenic symptoms, such as central spinal claudication or radicular claudication when standing or sitting, either on the concave side owing to foraminal (true) stenosis, or on the convex side owing to dynamic overstretching of the spinal nerve (Aebi, 2005; Kotwal et al, 2011).

Treatment depends on the patient's current quality of life and functional disability. The clinician should start with a conservative approach (Everett and Patel, 2007); clinical and radiological monitoring should be organized, some individual may progress rapidly. Surgery can be considered depending on curve progression. Treatment for cosmetic reasons is rarely justified. Pain is treated as for non-specific LBP in the absence of specific evidence of differential effects in degenerative scoliosis. Asymptomatic patients require no treatment.

6.5 Sagittal imbalance

In contrast to frontal plane deviations, sagittal spine curvatures and their balance is a more recent concept (Roussouly et al, 2005). Spinal balance is maintained by keeping the centre of gravity positioned over the femoral heads, ensuring minimal energy expenditure when upright. The extent of spinal curvature (lordotic and kyphotic segments) and inclination of the pelvis vary in the normal population (Boulay et al, 2006). Facet joint osteoarthritis, disc or vertebral body height loss or spondylolisthesis (Labelle et al, 2011) can result in decreased lumbar lordosis and an increase in thoracic kyphosis. Sagittal imbalance has been defined as a C7 plumb line deviation of >5 cm (line joining the centre of the C7 and the S1 superior plateau) anteriorly (or posteriorly), but this classification requires whole spine radiographs in the upright position. A variety of spinopelvic parameters can be derived (figure 9).

Figure 9 Spinopelvic parameters. PI, pelvic incidence; PT, pelvic tilt; SS, sacral slope. (Courtesy of Professor J-C Le Huec.)

$$PI = PT + SS$$

To prevent falling over, spinal sagittal balance must be maintained, and several compensatory mechanisms have been described: pelvic retroversion; hip hyperextension; knee flexion; ankle extension; lumbar retrolisthesis and reduction of the thoracic kyphosis (Barrey et al, 2011*). It has been suggested that lumbar pain radiating into the leg, which may mimic neurogenic claudication, can arise from muscle tension secondary to sagittal imbalance. Incomplete restoration of sagittal balance has been suggested as a cause of persistent back pain and of disease in adjacent segments after spinal fusion. Conservative treatments have been designed aiming to decrease tension of back extensors by favouring pelvic retroversion (eg, through stretching of psoas muscles) and restoring hamstring and quadriceps muscle length. They include mobilisation exercises for flexible segments and core stability strengthening (figure 10).

Figure 10 Sagittal imbalance compensated by maximum hip extension and knee flexion. (Courtesy of Professor J-C Le Huec.)

6.6 Facet syndrome

Pairs of facet joints (zygapophysial or z-joints) are found at each level with hyaline cartilage articular surfaces, a fibrous joint capsule with a synovial layer, anteriorly limited by the ligamentum flavum and often meniscoid structures. Facet joints are innervated by the medial branch (or dorsal branch at the L5 level) of the primary dorsal ramus (L1–L4) of the spinal nerve; each joint is innervated by its own level and the level above (sometimes also one level below).

The facet syndrome is a clinical entity describing facet joint pain and, in some cases, ‘referred pain’ (in the lower extremity) that can be misinterpreted as radicular pain. This is most common at the L4–L5 and L5–S1 levels in the lumbar spine. The syndrome has been known since 1911, but the term ‘facet syndrome’ was coined by Ghormley in 1933 (Manchikanti and Singh, 2002). It is thought to account for 5–15% of non-specific LBP, with increasing prevalence in the elderly population (van Kleef et al, 2010).

There is no pathognomonic clinical test for facet joint pain. Pain on extension from the flexed position, particularly during lateral rotation, or pain on extension that is more severe than on flexion, might suggest pain originating from facet joints. However, the validity of these tests has not been definitively proven, and there remains divergence of professional opinions on which tests should most influence clinical decisions (Mars et al., 2015). Radiographic evidence of facet joint osteoarthritis does not usefully predict facet joint pain. Pain might originate from facet joints in people without osteoarthritis, and, as is also the case with other joints such as the knee, radiographic osteoarthritis is often pain-free. Possible contributions to facet syndrome from repetitive minor trauma, inflammation, hypo- or hypermobility remain unproven. Analgesic response to a local anaesthetic nerve block might be considered as the primary diagnostic criterion, and might be anticipated to

predict benefit from radiofrequency denervation. Clinical assessment including physical examination however is required to select patients and spinal levels for interventional diagnostic testing. Diagnostic blocks require imaging (fluoroscopy, CT scan or ultrasound) to ensure accurate placement. Positive has been defined as a pain reduction of 50% to >80% during the half-life of the local anaesthetic used (Cohen and Raja, 2007; Pampati et al, 2009). Placebo effects of injections can be high, so pain relief following diagnostic block procedures need not necessarily indicate a specific origin of pain. Double diagnostic blocks (for example, using two anaesthetic drugs with different half-lives) have been proposed to improve specificity. Diagnostic blocks might only be cost-effective in clinical practice where the outcome will determine whether invasive treatments such as radiofrequency denervation will be pursued.

Conservative treatment is multimodal and might include manual therapy (mobilisation/manipulation) and physiotherapy (range of motion gain) in addition to other treatments recommended for non-specific LBP. Patients with pain which is of at least moderate severity, persistent (ie not likely to improve spontaneously), and which is localised rather than originating from multiple spinal structures might be considered for radiofrequency denervation (*Ward et al., 2016). Radiofrequency denervation would usually be reserved for those in whom more conservative treatments have been ineffective, and who display positive responses to diagnostic blocks. Intra-articular and periarticular glucocorticoid injections into facet joints have often been performed in the past, although numerous systematic reviews and previous guidelines have failed to demonstrate cost-effectiveness (*Ward et al., 2016). Benefits even from radiofrequency denervation might not be sustained, possibly due to regrowth of nerves into denervated structures, or to complex and changing origins of pain over time. The benefits of multiple or repeat procedures remains unproven. More research is required to define the optimal assessment and holistic management of facet syndrome.

7 Neurological syndromes associated with back pain

7.1 Lumbar radiculopathy

7.1.1 Definition

Many synonyms for lumbar radicular pain have been used—for example, ischias pain, nerve root pain, nerve root entrapment, sciatic neuralgia or, most commonly, sciatica. Radicular pain is the most accurate term and is defined as ‘pain perceived as arising in a limb or the trunk caused by ectopic activation of nociceptive afferent fibres in a spinal nerve or its roots or other neuropathic mechanisms’. A common cause of lumbar radicular pain is a herniated disc and thus ‘lumbar radicular pain due to herniated disc’ seems to be the most appropriate terminology (van Tulder et al, 2010*). The term ‘sciatica’ refers to a symptom rather than an underlying pathogenic mechanism, and is used to describe pain referred from the lower back to the leg below the knee, in the distribution of the sciatic nerve innervation. Sciatica might or might not be associated with herniated lumbar disc.

7.1.2 Epidemiology

The lifetime incidence of sciatica varies from 13% to 40%, with an annual prevalence of 1–5% (Konstantinou et al, 2008). The incidence peaks in the 45–64-year age group and the odds ratio of an episode of sciatica increases by 1.4 for every additional 10 years of age, up to the age of 64. An estimated 5–10% of patients with LBP also have sciatica, but most patients with back and leg pain do not have lumbar radicular pain due to herniated disc, even when the pain is radiating to the foot. From twin studies, heritability has been estimated as about 20%. Few high-quality studies have been published on environmental and personal factors. In a prospective study of adolescents followed up for 30 years, none of the studied factors, including participation in sport, was associated with the development of sciatica (Rivinoja et al, 2011). However, being overweight and current tobacco use among men and obesity in women were associated with an increased risk of a second-time hospitalisation for surgical treatment of sciatica in adulthood. In cross-sectional studies, an association with certain occupational factors has been reported, including an awkward working position, such as in a flexed or twisted trunk position, and driving or working with the hands above the shoulders. A possible role of tobacco use has been inconsistently reported.

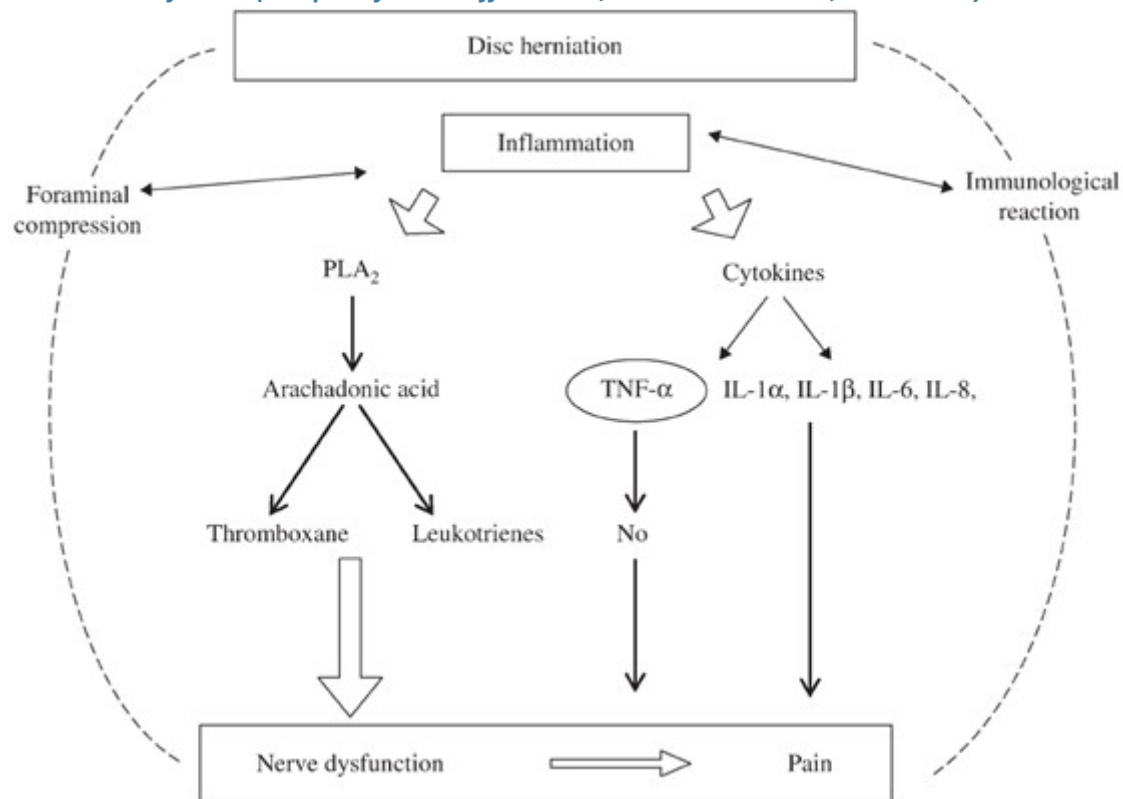

7.1.3 Pathophysiology

The intervertebral disc has been implicated in the pathophysiology of sciatica through different mechanisms (Figure 11). At first, the assumption that the protruded disc exerted pressure on the sciatic nerve root was commonly accepted. Therefore, treatment was surgical decompression. However, as early as the mid-20th century, it was suggested that pressure on a nerve results in loss of function and is rarely associated with pain. Several lines of evidence support this hypothesis: disc herniation with apparent neural compromise are common findings in asymptomatic patients, and also, symptomatic patients with disc herniation may improve without any alteration of the original pathology.

Although benefit from surgical decompression in carefully selected patients suggests that mechanical factors do play a role, additional inflammatory and/or immunological mechanisms are also involved (figure 5). Cytokines have been implicated in this inflammatory process (Valat et al, 2010). Tumour necrosis factor α (TNF α) may be the cytokine most strongly associated with the proinflammatory properties of the nucleus pulposus, as shown in many different animal models. The presence of interleukin 1 α (IL-1 α), IL-1 β , IL-6, IL-8 and TNF α in homogenates of discs removed from patients with sciatica has been documented. TNF α was significantly increased in the epidural fat surrounding the inflamed nerve root in patients with sciatica compared with controls (Genevay et al, 2008). There is preliminary evidence that TNF α blocking antibodies might reduce the pain of sciatica and hasten recovery in people with acute disc prolapse (Williams et al., 2013), although more detailed cost-effectiveness studies would be required to justify introduction of this treatment into routine clinical practice.

Immune mechanisms within the central nervous system also contribute to the development of neuropathic pain. Extensive preclinical data have linked the development of glial cell activation within the spinal cord to the development and maintenance of neuropathic pain, and novel pharmacological approaches that reduce neuroimmune activation have potential as analgesic agents. .

Figure 11 An overview of the pathogenesis of lumbar radiculopathy. IL, interleukin; PLA₂, phospholipase A₂; TNF, tumour necrosis factor. (Adapted from Stafford et al, Br J Anaesth 2007;99:461–72.)

7.1.3.1 Other causes of sciatica

Sciatica, as a symptom, need not always indicate radicular pain and non-discogenic causes should be considered even in people with imaging evidence of herniated intervertebral disc. MRI findings are not uncommon in asymptomatic individuals, and an important contribution from other mechanisms to sciatic symptoms might compromise response to specific interventions such as surgery, and might rarely indicate a need for other specific treatments. Red flags for sciatica do not differ from those for LBP.

Pain referred below the knee might originate from neuronal activation distal to the spine. Nerve irritation through the piriformis muscle has been proposed (piriformis syndrome), although definitive diagnostic classification is controversial. Claudicant features might indicate spinal or foraminal stenosis, but might also results from peripheral vascular disease (see below). Hip pain can sometimes be experienced radiating below the knee, and hip examination is an essential component of assessment of a person with sciatica. Where sciatica reflects lumbar radicular pain, non-discogenic causes should be considered. The main causes of non-discogenic sciatica are listed in table 9.

Table 9 Non-discogenic causes of sciatica (Adapted from Stafford et al, Br J Anaesth 2007;99:461–72)

Causes	Description
Malignancy	Metastatic, sarcoma, neuroma, hemangioblastoma
Infection	Abscess, discitis, epiduritis, herpes zoster radiculitis, Lyme radiculitis
Vascular compression	Epidural thrombosis, abnormal pelvic venous plexi, gluteal artery pseudoaneurysm
Muscular compression	Piriformis syndrome
Bony compression	Degenerative spinal stenosis, foraminal stenosis Osteophytes of the sacroiliac joint
Epidural	Epidural lipomatosis, epidural adhesions (after surgery)
Gynaecological	Pelvic endometriosis, uterine fibroid
Metabolic	Diabetic painful amyotrophy, alcoholic neuropathy

7.1.4 Diagnosis

Sciatica is mainly diagnosed by history taking and physical examination (van Tulder et al, 2010*). By definition, sciatica is characterised by radiating pain that follows a dermatomal pattern. A patient should be asked about the distribution of pain and whether the pain radiates below the knee. Sensory symptoms additional to pain, for example paraesthesiae or reduced sensation, increase specificity for radiculopathy. Associated LBP is common, but is not always present and is often not the dominant symptom. In addition to ruling out red flags (identical to LBP), the history should determine the localisation and severity of pain, loss of strength, sensitivity disorders, duration, influence of cough and effect on daily activity. Progressive neurological deficit, particularly motor weakness, is an indication for early intervention, whereas gradual improvement might favour more conservative approaches.

Physical examination largely focuses on neurological symptoms. The diagnostic value of history and physical examination has not been well studied. No single history item or physical examination test has both high sensitivity and specificity to predict a disc origin of sciatica. The most common examination tools are the SLR test and the crossed SLR. SLR has a sensitivity of 0.92 and a specificity of 0.28 in surgical cohorts (van der Windt et al, 2010). As expected, results from studies using imaging are less homogeneous. Crossed SLR showed a high specificity (pooled estimate 0.92), but low sensitivity (0.28). The bell test (reproduction of the radicular pain by pressure applied with the thumb between the spinal processes of L4 and L5 or between L5 and S1) has a specificity of 63% and a sensitivity of 50%. The hyperextension test (reproduction of the radicular pain in standing position by passive mobilisation of the trunk in extension with the knees in extension) has a specificity of 70% with a sensitivity of 45%. Overall, if a patient reports a typical pain radiating to one leg combined with a positive result on one or several clinical tests indicating nerve root tension or neurological deficit, the diagnosis of sciatica by herniated disc is justified.

7.1.5 Imaging

Imaging is useful if the results influence further management. In acute sciatica, the diagnosis is based upon history taking and physical examination. At this stage, the treatment is mostly non-surgical and imaging is indicated only if there are red flags or indications that the sciatica may be caused by underlying diseases, such as malignancies or infections rather than disc herniation. Otherwise imaging should be performed when needed to direct specific treatments, for example transforaminal epidural injection or surgical intervention. A good correlation between pain distribution and the level and side of disc herniation is important to validate the diagnosis before introducing more invasive treatment. Clinicians should keep in mind that disc herniations detected by MRI or CT scan are highly prevalent in the general population (up to 40%) without sciatica. It must be recalled also when considering whether imaging findings are likely to explain symptoms that at each lumbar level, foraminal and extraforaminal disc herniation are in contact with the cranial nerve root, whereas paramedian disc herniation is in contact with the caudal nerve root (figures 6 and 12).

Figure 12 Topography of the nerve root at the lumbar level (example L4–L5 disc). A disc herniation located in the extraforaminal (4) or foraminal (3) area is in contact with the L4 nerve root, whereas when located in the paramedian (2) or medial (1) area, it is in contact with the L5 nerve root. IVD, intervertebral disc.

Furthermore, no lumbar disc herniation can be identified on MRI or CT scan in some patients with sciatica. MRI may be slightly more accurate than CT scan at diagnosing lumbar disc herniation because soft tissue in the spinal canal is better characterised. Some authors also favour MRI because CT scan has a higher radiation dose. On the other hand, bone tissue is better analysed by CT scan. Finally, radiography is not recommended for the diagnosis of lumbar disc herniation.

7.1.6 Natural history

Most patients with acute sciatica respond to conservative symptomatic management and the sciatica resolves over a period of weeks to months (Valat et al, 2010). Data from an old randomised trial of non-surgical interventions indicated that 50% of patients with very acute sciatica included in the placebo group reported improvement within 10 days, about 75% reported improvement within 4 weeks and 60% returned to work. However, up to 30% of patients continued to have pain for 1 year or longer. When patients with an average of 4 months of leg pain were randomised into two groups, immediate surgery or conservative treatment for 6 additional months, those assigned to early surgery recovered more quickly (Peul et al, 2007). At 1 year, the percentage of recovery reached 95% for both groups, but one-third of patients in the group receiving prolonged conservative treatment underwent surgery between 6 and 12 months after randomisation because of intractable leg pain. The long-term rate of persistent pain (back and/or leg pain) is between 10% and 20%.

No early-stage predictors of poor outcome have been clearly identified. In particular, baseline imaging is not a good predictor of symptomatic outcome in sciatica. Abnormalities on MRI resolve more completely with large disc herniations than with bulging discs, and disc sequestrations are more likely to resolve partially or completely than herniations without signs of migration (disc protrusions). For disc herniation or sequestration, 76% might completely or partial resolve on MRI at 1 year compared with 18% for generalised or focal disc bulge. In summary, large disc protrusions, far from indicating a need for early invasive treatment, might indicate a likely good prognosis with conservative management.

7.1.7 Non-surgical treatments

Conservative treatment for sciatica is primarily aimed at reducing pain and nerve irritation, either by medications or glucocorticoid epidural injections. Systematic reviews have found no support for opioid analgesia, bed rest, exercise therapy, traction and percutaneous discectomy (Lewis et al, 2013, *Ward et al., 2016). Patient education/advice is an expected component providing context to any treatment, but is not effective for sciatica when used alone. Indeed one systematic review found that conservative treatments do not clearly improve the natural course or reduce symptoms of sciatica in most patients (van Tulder et al, 2010*). However, there is reasonable evidence that non-opioid drugs, epidural injections and disc surgery can be effective (Lewis et al, 2013, *Ward et al., 2016).

Many patients with sciatica also have back pain, and back pain can often persist after resolution of sciatic symptoms. Therefore, where specific evidence of benefit in sciatica is absent, treatment as for LBP might seem appropriate. Many of the clinical trials in LBP did not exclude patients with sciatica, and guidelines often refer to management of LBP with or without sciatica (*Ward et al., 2016). Concerns have been raised that exercise might lead to extension of disc prolapse, but, on the other hand, fear of exercise predicts poor prognosis in people with LBP with or without sciatica (*Hill et al., 2011). Little difference in pain or functional outcome has

been shown between bed rest and advice to stay active. The addition of physical therapy to general practitioner care for sciatica had benefits on 'patient-perceived global effect', with a rate of improvement of 79% vs 56% in the control group at 1 year (Luijsterburg et al, 2008). Symptom-guided exercises in addition to information and advice to stay active was followed by a global improvement in 80% of participants at 8 weeks (compared to 60% those receiving sham exercises), although no difference in pain or function was found (Albert et al, 2012). Specific benefit from guided exercises for sciatica therefore remains inconclusive, but the limited evidence from controlled trials does not support the fear that exercise is harmful. Onset of pain during activity does not indicate that continuing activity will exacerbate damage. Indeed, the loss of strength and proprioceptive reflexes that can follow inactivity might increase the risk of further injury in the future. Therefore, bed rest is no longer widely recommended (Valat et al, 2010), and patients are encouraged to maintain normal activities where possible.

Only a few studies have examined medication specifically for sciatica. Mechanistic classification of sciatica as neuropathic (rather than nociceptive) pain encourages generalisation of findings from randomised controlled trials in other painful neuropathic conditions. Taking this approach, tricyclic antidepressants such as amitriptyline in doses up to 75 mg at night, gabapentinoids or selective serotonin and noradrenaline reuptake inhibitors (SSNRIs, e.g. duloxetine, milnacipran) might be considered for sciatic pain. However, it is unclear that neuropathic pain represents a single entity, and therefore treatments for one form of neuropathic pain might not work for others. Topical capsaicin can be helpful for neuropathic pain originating in cutaneous afferents, but would not be expected to help pain from deep structures such as in sciatica. An old study on gabapentin (3 × 300 mg/day) found a positive effect on pain, whereas an early trial on pregabalin did not show any effect despite a complex design (Baron et al, 2010). A further randomised controlled trial suggested similar efficacy of oral gabapentin to glucocorticoid epidural injection for sciatica (Cohen et al., 2015). Some studies focusing on sciatica reported a positive, short-term benefit from NSAIDs, consistent with inflammatory mechanisms in acute sciatica. Diazepam had no additional effect on hospitalised patients with sciatica compared with those receiving a placebo and the median duration of hospital stay in hospital was shorter (8 vs 10 days; $p = 0.008$) in the placebo arm. Despite benefit from epidural glucocorticoid injection (see below), systemic glucocorticoids are no better than placebo for sciatica, possibly because adequate drug levels cannot be achieved local to the involved nerve root.

The most extensively evaluated conservative treatment for sciatica is the epidural injection of glucocorticoids. Epidural injections are recommended as part of the treatment for acute and severe sciatica (Kreiner et al, 2014*, *Ward et al., 2016), although controversies remain. There is fair evidence that epidural injections are effective in the short term (<3 months), but poor evidence of any long-term effectiveness (Pinto et al, 2012). Epidural glucocorticosteroids is thought to reduce pain by reducing perineural inflammation, and if uncontrolled inflammation is a cause of long term nerve damage (neuropathy), then it might be expected that

they might reduce long term pain. Furthermore, short term analgesia might permit an early return to normal activity. However, the contribution of inflammation or physical activity to persistence of sciatica remains unproven. Glucocorticosteroids injections in other contexts (e.g. intra-articular) typically produce only temporary benefit. Without further evidence, it might be most appropriate to consider epidural injection as a form of analgesia, alongside oral medications, that might hasten recovery rather than a disease modifying intervention that would remove a need for surgery or risk of long term symptoms. Epidural injections do not significantly improve LBP and therefore their indication is severe sciatica, and they should not be offered for severe disability mainly due to LBP.

Different procedures are all referred to as 'epidural', whether injection is directed through the sacral hiatus (caudal epidural), interlaminar or transforamina (periradicular). There is evidence that injections performed without imaging guidance are less effective. Ultrasound may be used to guide caudal epidural injection, whereas fluoroscopy (or CT imaging) is required for the transforaminal approach. It has been suggested that transforaminal injection might be more effective than caudal epidural, particularly for higher lumbar root involvement (e.g. L4). Tracking of injectate to more rostral levels of pathology might be incomplete via the caudal route. Randomised controlled trials provide some, but inconclusive evidence for this assertion. Transforaminal injection requires access to specialist facilities for imaging, whereas caudal epidural might be offered within primary care. Cases of spinal cord infarction after lumbar foraminal injections have been reported, mainly in patients with previous back surgery at the injected level. Definitive guidance cannot therefore be provided on which type of epidural should be offered, but delays to more definitive treatment by sequentially administering multiple epidural injections through differing routes is clearly undesirable.

7.1.8 Minimally invasive interventions

Minimally invasive interventions for sciatica are mainly procedures of disc decompression performed through a needle. The goal is to remove or destroy tissue from the centre of the disc in order to decrease pressure exerted by the disc herniation on the nearby nerve root. To achieve this, these techniques are limited to contained disc herniation (also called subligamentous disc herniation as they have not crossed the posterior longitudinal ligament that lies between the disc and the epidural space). Chemonucleolysis (intradiscal chymopapain injection) has been used. According to a Cochrane review, it is better than conservative treatments, including steroid injections, but inferior to surgery. However, it has now been abandoned in most parts of the world because of its potential side effects (anaphylaxis). Several different techniques have been developed based on the same concept, including laser discectomy, which might have similar efficacy to open surgery (Brouwer et al., 2105), although further evidence is desirable.

7.1.9 Surgical treatment

Removal of disc herniation, part of the disc or correction of foraminal stenosis are the main objectives of surgical procedures for sciatica. The purpose is to eliminate the suspected mechanical cause of nerve root compression. Treatment is aimed at decreasing the leg pain and corresponding symptoms, but not at reducing back pain. Indications for immediate surgery include cauda equina syndrome or progressive motor loss (with muscle strength <3 on a 6-point scale). Randomised controlled trials have compared surgery with usual conservative care, epidural injection or early surgery with prolonged conservative care (Jacobs et al, 2011). Unfortunately, however, study quality has often been limited. Early surgery appears to provide better short-term relief of leg pain than prolonged conservative care, but no difference was seen at 1 or 2 years. From a societal perspective, early surgery might be more cost-effective because of reduced loss of productivity.

7.1.10 Prognosis

In studies performed in secondary or tertiary centres, the rate of total clinical recovery (pain and function) following surgery varies between 40% and 50% at 1 and 2 years. Identified factors of poor prognosis are the presence of back pain at baseline; intensity of back and leg pain; general health (comorbidities); fear-avoidance beliefs and the SLR test result. Results from a randomised controlled trial showed that recovery from motor deficit occurs in 70–80% of patients at 1 year (Overdevest et al, 2013). Although recovery was faster in surgically treated patients, there was no difference between groups at 1 year.

7.1.11 Summary of care and shared decision-making process

In clinical practice, information about the condition, pain treatment using NSAIDs, opioids and neuropathic pain treatment and epidural injection when severe pain persists after a few weeks, set the scene for conservative treatments. Physical therapy is important to encourage maintenance of activity, particularly when back pain becomes the main source of pain and disability. Three months after onset, if severe sciatica persists despite conservative treatment, the possibility of a surgical intervention should be considered. Physicians and patients should consider fully the benefits and harms of all treatments, and the patient's treatment preference may have a direct positive influence on the magnitude of the treatment effect. This process is known as shared decision-making. To ensure the quality of information necessary for an informed choice, a list of items that should be discussed during the consultation is provided in box 3 (Sepucha et al, 2012). This must be part of a dynamic process that should be revisited at each consultation.

Box 3 Items forming the basis of informed decision-making for surgery in patients with continuing sciatica

1	Herniated disc does not become worse during normal activities
2	Over time, with or without surgery, the leg pain caused by a herniated disc usually improves
3	Lots of bed rest does not help to relieve pain caused by a herniated disc
4	Over-the-counter pain medicine helps some individuals to relieve the pain caused by a herniated disc
5	Surgery is most likely to provide faster relief from pain caused by a herniated disc
6	Between 10-30% of individuals who undergo surgery for a herniated disc will have the same or more pain after surgery
7	Failure to relieve pain, dural puncture, infection, and hematoma are the most common complications of surgery for a herniated disc
8	Without surgery, almost no patient will develop permanent weakness that results in not being able to walk at all
9	The rate of serious complications in individuals who undergo surgery for a herniated disc is between 1–5 %
10	The rate of recovery from leg pain at five years is the same, with or without surgery
11	Stomach ulcer, excessive bleeding, and kidney problems are possible side-effects when using over-the-counter pain medicine for a long time

Reproduced with permission from Sepucha et al, Spine 2012;37:834–41. To this might be added that prescribed medications might also relieve pain caused by a herniated disc, and clarification that the listed adverse events of over the counter analgesics refers to non-steroidal anti-inflammatory drugs.

7.2 Neurogenic Claudication

Lumbar spinal stenosis with neurogenic claudication is one of the most commonly diagnosed and treated pathological spinal conditions of the elderly population and is expected to rise even further with the increased ageing of the population (Watters et al, 2008). This neurogenic syndrome is hypothesised to result from the compression of the vasa nervorum of the nerve roots in the spinal canal. A diagnosis of the clinical syndrome of lumbar spinal stenosis requires both the presence of characteristic symptoms and signs and radiographic or anatomical confirmation of narrowing or stenosis of the lumbar spinal canal (Genevay and Atlas, 2010*). As many people with radiographic or anatomical lumbar spinal canal stenosis may not have any symptoms, the clinical diagnosis is extremely important and an alternative diagnosis (table 10) must be ruled out before establishing the final diagnosis.

Patients with neurogenic claudication have a variable amount of pain or discomfort in the buttock, thighs, lower legs or feet, brought on by walking or prolonged standing. Typical features include improvement (or complete relief) with sitting or lumbar flexion (ie, leaning forward on a shopping cart) and worsening with lumbar extension (eg, walking downhill). Some individuals may have more subtle leg symptoms, including fatigue, heaviness, abnormal sensations, weakness or gait changes. Back pain is not always present and its relationship with anatomical canal stenosis remains controversial. The classic radiological picture on MRI or CT (less accurate) associated with neurogenic claudication is a narrowing of the spinal canal second to

degenerative changes (bulging disc, facet osteoarthritis and yellow ligament (ligamentum flavum) hypertrophy). It has been suggested that the surface area of the dural sac is more predictive of symptom severity than that of the spinal canal.

The clinical course of neurogenic claudication is often stable or only slowly progressive and most patients with mild or moderate pain have a favourable outcome with conservative treatment (Watters et al, 2008). Evidence for treatment benefit are mainly based on cohort study and expert opinion. Treatment of pain may be pharmacological, including medications recommended for neuropathic pain such as tricyclic antidepressants, gabapentinoids or SSNRIs. The risk: benefit ratio for analgesics can, however, be relatively high, given that people with spinal claudication might have little if any pain at rest despite severe symptoms on walking, and patients are often elderly and with comorbidities. Definitive evidence is still required that medical treatments can either reduce pain or increase walking distance. Physical therapy is a core treatment. Muscle reinforcement with attention to body posture aims to decrease lordosis, and so increase the spinal canal area in order to relieve pain (Ammendolia et al, 2012). Graded exercise can be helpful once the patient understands that the pain does not mean ongoing damage. It has been proposed that spinal claudicant pain might in part result from intermittent neuronal ischaemia rather than frank compression, and that stenosis reduces the capacity of spinal blood vessels to dilate during exercise. Certainly, patients should be discouraged from smoking. Glucocorticoid epidural injections have been found to not be of benefit for chronic spinal claudicant pain, and therefore are not recommended (Radcliff et al, 2013, *Ward et al, 2016). Decompressive surgery may be considered for severe cases and there is good evidence that it is better than 'standard care', although risks of major spinal surgery should be weighed carefully against likely benefits for each individual patient (Weinstein et al, 2008a). Less invasive interspinous devices that increase kyphosis locally are sometimes proposed in stenosis that affects only one disc level in people with serious comorbidities. Overall, evidence for surgical and non-surgical treatment to improve walking ability is of low or very low quality (Ammendolia et al, 2014).

Table 10 Main differential diagnoses for buttock and leg pain with or without radiating leg pain in an elderly patient

Diagnosis	Clinical characteristics
Spinal disorders	
Lumbosacral radicular pain secondary to nerve root impingement	Lumbosacral radicular pain (with or without low back pain) in the setting of lumbar disk herniation may be accompanied by a positive straight leg raise test or femoral stretch test
Referred pain from lumbar spine structures	Low back pain and proximal lower extremity referred pain in non-radicular pattern
Lumbar vertebral compression fracture	Low back pain or thoracic pain in an older patient, often of acute onset, with or without specific history of recent injury
Extraspinal disorders: musculoskeletal diagnoses	
Sacral fracture	Buttock pain uni- or bilateral, with or without low back pain, with or without specific history of recent injury
Sacro-iliac joint disease	Buttock pain with or without posterior thigh radiating pain. Inflammatory pain or mechanical pain depending on the disease (spondyloarthritis, infection, or mechanical problem).
Hip joint referred pain	Groin pain, buttock pain, with or without low back pain, referred symptoms are mainly proximal to the knee, often with weight bearing; may limp and have limited internal rotation of the hip
Trochanteric bursitis	Lateral hip and thigh pain, with tenderness over the greater trochanter; low back pain may or may not be present
Piriformis syndrome	Pain localized over the piriformis muscle in the buttocks, with or without radiating posterior buttock and lower extremity pain; tight hip external rotators may be appreciated
Myofascial referred pain	Pain can be reproduced by pressing on tender points or trigger points (e.g., <i>gluteus medius</i> and <i>minimus</i>)
Extraspinal disorders: other diagnoses	
Intermittent claudication due to peripheral arterial disease	Leg muscle discomfort, cramping, tightness, or tiredness in the buttock or lower extremity that is induced by exercise, often consistently reproduced after walking a certain distance, relieved rapidly with rest, eased with standing, and not affected by trunk posture; decreased pulses or impaired ankle brachial index may be present
Peripheral neuropathy	Pain, numbness, and tingling in the distal lower extremities, particularly the feet and ankles, not substantially affected by posture or exertion
Visceral referred pain	Low back pain, lower extremity pain, or both may be referred from structures in the abdomen and pelvis, including the gastrointestinal tract and genitourinary system

SUMMARY POINTS

- Low back pain (LBP) is an extremely common symptom. Most people will not require any treatment.
- Excluding the causes for specific LBP (fracture, tumour, spondylodiscitis, spondyloarthropathy) is the first and most important step. Investigations (primarily radiological examinations) are only performed when 'red flags' have been identified (through medical history and physical examination), or where needed to guide specific interventions.
- Patients with associated neurological symptoms (lumbar radicular pain or neurogenic claudication) should be managed specifically.
- Once these conditions are excluded, patients are classified as having non-specific LBP. CT or MRI descriptions (eg, discopathy, osteoarthritis, ...) have no influence on the diagnosis. The presence or absence of non-radicular leg pain (radiating pain) does not affect the diagnosis or the treatment.
- Non-specific LBP is usually divided into acute (up to 4 weeks), subacute and chronic LBP (>3 months); however, many patients will develop an intermittent pain syndrome.
- A subgroup of patients with intermittent or chronic non-specific LBP will develop chronic disabling pain. Hence detecting factors predicting chronicity is the second most important step in managing patients with non-specific LBP.
- These factors are categorised in three main domains: psychological, social and professional. They must be taken into account when designing the treatment plan.
- Information, reassurance, advice to stay active, analgesia are the main points for the treatment of acute non-specific LBP.
- Exercise therapy, spinal manipulation and a specific multidisciplinary programme (ie, that includes a psychological component) are recommended for the treatment of subacute and chronic LBP. For the latter, additional recommended therapeutic interventions include yoga, behavioural therapy and active rehabilitation as well as a self-management programme.
- Spinal injections (epidural injection for sciatica) or radiofrequency denervation of facet joint structures may be considered in carefully selected cases, and referral for a surgical opinion may be considered if severe lumbar radicular pain persists beyond 3 months despite optimal care.
- Lumbar radicular pain and neurogenic claudication require specific attention as they are associated with a different epidemiology, physiopathology, prognosis and treatment plan.
- Additional entities should be recognised as they may, at times, influence the treatment plan: spondylolysis/listhesis, Scheuermann's disease, idiopathic and degenerative scoliosis, diffuse idiopathic skeletal hyperostosis, sagittal imbalance, Modic I endplate modification, facet syndrome.

IN-DEPTH DISCUSSION I

**Multi/inter-disciplinary approaches to chronic
lumbar back pain**

Non-specific chronic low back pain (NSLBP) has become a worldwide health problem. Encouraging physical activity is a cornerstone of musculoskeletal rehabilitation, and supervised exercise therapy is recommended as a first-line treatment in the management of chronic LBP. These mono-disciplinary approaches are of limited efficacy to achieve significant pain reduction, improving disability and return to work. Following the recognition of the importance of the bio-psycho-social perspective to tackle chronic pain patients in general, and NSLBP in particular multi- or interdisciplinary rehabilitation treatment programs have been implemented. Whereas the biomechanical approach relies on classic physiotherapy, multi- or interdisciplinary rehabilitation programs are built on approaching the patient psychologically and functionally (1).

Interdisciplinary programs should offer an integrated rehabilitation intervention plus a psychological and/or social/occupational component (2) seeking a common goal. Often this will include physiotherapists, occupational therapists, psychologists and/or psychiatrists, pain clinicians, rheumatologists and/or physiatrists. By definition multidisciplinary interventions include multiple actors. However, an interdisciplinary treatment additionally comprises proficient knowledge of each other team members' expertise (3). This diverse group of clinicians, each contributing to the patients' care, should meet at least weekly to discuss the patients' progresses (4). Cognitive behavioural therapy (CBT) may also be included (5). Inviting spouses to participate in the rehabilitation (spouse assisted strategies) have also been proposed (6). The intensity of the programs varies between 12 and 50 hours per week, most of the time conducted over 2 to 4 weeks (7,8).

Not all patients with non-specific low back pain (NSLBP) need a multidisciplinary approach and not all of the patients recruited will adhere to such a program. Compliance is difficult to predict (9). Early detection of the ideal participant (i.e. responder) would be useful; some tools and criteria have been put forward: Guidelines from the USA recommend including patients suffering from « persistent and disabling back pain » whereas European guidelines largely opt for any chronic NSLBP patients. It has also been recommended to implement such a program to help decision making before undertaking surgery; mid-term results seem promising when comparing surgery versus multidisciplinary approach for NSLBP favouring the latter (10). The inclusion of subacute NSLBP in multidisciplinary rehabilitation program (MDRP) is controversial as these programs may not be as effective (11). Focusing on patients having a high level of modifiable risk factors has been suggested (12). Modifiable risk factors may include anxiety, fear avoidance behaviour, catastrophism, bothersomeness and biomechanical issues.

The goal of a rehabilitation program explicitly addressing bio-psycho-social factors is mainly focused on decreasing functional limitations and promoting return to work. Improved self-management and self-efficacy has been revealed as key elements (13). The most recent Cochrane review on systematic reviews of RCT's comparing MDRP and "usual (i.e. individual) care "reveals a significant effect on pain and disability reduction (14). For most studied outcomes, the treatment effect size seems to be moderate (13).

Concerning return to work (RTW) a meta-analysis found only a small effect with possible publication bias (15). When analyse was limited to the 5 studies from Scandinavian countries (countries with similar social setting) the homogeneity was good and the effect on RTW was found clinically significant. A more recent meta-analysis concluded that the effect on work equates to a person having roughly double the odds of being at work after 12 months if they received a MDRP rather than a physical treatment (14).

Limited effectiveness has been shown on the long-term. Whereas M. Van Middelkoop et al. (16) found no significant improvement after five years compared to an active treatment regimen Van Hooff et al. (8) underlined reduced use of medication two years after the program. Others found moderate effect on ICF levels of impairment (17), less subjective disturbance in activities of daily life (8), but no impact on return to work. Interestingly no difference was shown at 9 years follow-up comparing surgical fusion versus interdisciplinary rehabilitation, clearly questioning the place of surgical interventions in these patients (18). The risk of experiencing adverse events was obviously higher in the surgical group.

In a systematic review on guideline-endorsed treatments for low back pain, MDRP were found to be cost-effective (19). This was confirmed in a recent large German study (20). Compared to a brief intervention (6 hours, mainly directed to reassuring patients) performed in a population of patients (partly or fully) on sick leaves for 4 to 12 weeks, Jensen et al. found that MDRP was cost-effective only in a subpopulation of patients at risk of losing their job or having little impact on their work situation (21). In a large (over 1600 patients) cohort of sick-listed (50% of them fully sick-listed) chronic NSLBP patients still having work contract at baseline, the only modifiable factor that predicts full return to work at 1-year was “more work-participation” at baseline (22).

In conclusion, multidisciplinary rehabilitation programs for chronic low back pain are effective in reducing functional limitations and improving return to work. Overall the clinical effectiveness is at best moderate and no significant change is to be expected beyond one year. The exact composition of the interdisciplinary group, the best time to perform the intervention, as well as the intensity and the duration of the treatment are yet to be defined on solid evidence.

Low back pain and associated syndromes

Federico Balagué, Maximilian Schindler, Stéphane Genevay

A previous version was coauthored by Francois Rannou, Serge Poiraudau, Yves Henrotin, Christelle Nguyen, Stéphane Genevay

IN-DEPTH DISCUSSION II

Symptomatic lumbar spinal stenosis

Neurogenic claudication and radicular leg pain are the clinical syndromes associated with lumbar spinal stenosis (LSS). On the one hand, lumbar spinal stenosis is frequently found in asymptomatic patients and on the other, up to 20% of older adults complain of lower extremity pain in the setting of low back pain. However, there are many other causes of lower leg pain, even in the presence of low back pain, that are not related to LSS. Because neurogenic claudication and radicular leg pain may require specific treatments (including surgery), reaching the correct diagnosis is paramount.

There are several classifications of spinal stenosis. The most widely used differentiates primary stenosis, caused by congenital abnormalities, from secondary, acquired, stenosis caused by degenerative changes, trauma, surgery or infection. The most common form of secondary stenosis results from slowly progressive degenerative changes affecting the facet joints (hypertrophy), the ligamentum flavum (hypertrophy secondary to fibrosis) and disc (decreasing height, bulging). These degenerative changes may result in stenosis of the central canal or/and of the foramen. Central stenosis mainly affects the three lower levels of the lumbar spine; its clinical expression will mainly be neurogenic claudication and, sometimes, cauda equina syndrome. Foraminal stenosis most commonly affects L5 nerve roots because the L5-S1 foramen has the smaller foramen/root area ratio; pain arising from foraminal stenosis will be of the radicular type relatively similar to radicular pain related to disc herniation. In addition to these anatomical changes, LSS has a dynamic component. The area of the central canal and of the foramen increases with axial distraction and flexion and decreases with extension, resulting respectively in decrease and increase in local pressure.

Neurogenic claudication is thought to result from vascular compromise to the vessels supplying the cauda equina (central stenosis) or from pressure on the nerve root complex (lateral stenosis) by the degenerative changes. Experimentally, it has been shown that moderate constriction-induced pressure involving the cauda nerve roots will disturb their nutrition. There is almost no data on the potential role of inflammatory mediators in the pathophysiology of neurogenic claudication despite rapidly increasing rate of corticosteroid spinal injection in these patients.

Clinical symptoms and physical examination

As the frequency of LSS on imaging is high in the asymptomatic population, the diagnosis of neurogenic claudication has to rely first on clinical findings. A recent review of the literature found that in a population with a prevalence of the clinical syndrome of LSS of 45%, in addition to age (>70 years, likelihood ratio (LR) = 2.0 and < 60 years LR = 0.4), the most useful symptoms for increasing the likelihood of the clinical syndrome of LSS were: having no pain when seated (LR = 7.4), having unexplained urinary disturbance (LR 6.9), improvement of symptoms when bending forward (LR 6.4), the presence of bilateral buttock or leg pain (LR = 6.3) and neurogenic claudication (LR 3.7). Physical examination tests were less useful. However, a wide base gait (LR = 13), an abnormal Romberg test (LR 4.2) and induced pain by bending forward (LR 0.48) are additional

useful clues to reach the correct diagnosis. Although less studied, the loading extension test (reproduction of leg symptoms while maintaining moderate extension up to 30 seconds) may have some interesting specificity.

In a very recent case control study involving 1448 patients with a primary complaint of back pain, the authors found that the most diagnostic combination for the clinical syndrome of LSS included a cluster of 1) bilateral symptoms 2) leg pain more than back pain 3) pain during walking/standing 4) pain relief upon sitting and 5) age >48 years. Failure to meet the condition of any one of five positive examination findings demonstrated a high sensitivity of 96% and a low negative likelihood ratio (LR) of 0.19. Meeting the condition of four of five examination findings yielded a positive LR of 4.6 and a post-test probability of 76%.

Additional investigations

Once clinical symptoms and signs suggest neurogenic claudication, radiological investigations may be useful to confirm LSS. There are no definite radiological definitions of lumbar stenosis. It has been determined both from in vitro and in situ studies that the cross-sectional area of the dural sac above 70 to 80 mm² would be unlikely to cause symptoms. There are however conflicting results about the correlation between the cross-sectional area of the dural sac and the severity of clinical symptoms of neurogenic claudication. Electro-diagnostic studies are sometimes used in clinical practice, however these studies have low sensitivity and specificity for neurogenic claudication.

Conservative Treatments

The clinical course of mild to moderate symptomatic LSS patients is favourable in up to 50% of cases. There are few studies of conservative treatments. Patients are commonly treated according to recommendations published for chronic low back pain patients. Gabapentin might be the only exception. In a small randomized controlled study, the addition of gabapentin to standard therapy was shown to be superior to the addition of placebo in terms of pain and walking distance.

Rehabilitation programs are often used in addition to pain medication with the assumption that exercises might delay the consequences of deconditioning. Postural therapy (body posture) is also prescribed to enhance lumbar spinal canal diameters and relieve pain. There are no solid studies to sustain these approaches. There is only one randomized trial testing a complex combination of manual physical therapy interventions, exercise, and a progressive body-weight supported treadmill walking regimen. A positive effect was found on perceived recovery but not on pain or function.

There is good evidence that inter-laminar epidural corticosteroid injection without fluoroscopic guidance is ineffective. A recent systematic review suggests that epidural steroid injections provide limited improvement in short-term and long-term benefits in LSS patients. The addition of corticosteroids to bupivacaine does not

have an additional effect. Foraminal injection appears to be less effective in LSS than in patients with radicular pain due to disc herniation.

Surgical treatments

There is some evidence that inter-spinous devices and good evidence that decompressive laminectomy are better than “usual care”. Results of randomized trials comparing surgery and non-surgical care are often confounded by high rate of cross-over. A recent study showed no difference between the two groups but the non-surgical group followed a well-structured physical and education program. According to a systematic review the long-term success rate of surgery varies between 45% and 72%. In one randomized controlled study bilateral laminotomy was found to be superior to bilateral laminectomy in terms of pain relief but it had no additional beneficial effect on walking distance.

Predictors of poor surgical results are depression, cardio-vascular co-morbidities, scoliosis and associated disorder influencing walking abilities. Serious complications appear to be very rare in randomized controlled studies.

In a recently published RCT, a comprehensive post-surgical rehabilitation program failed to improve surgical results.

Shared decision making

As symptomatic LSS is a fluctuating chronic disease, the need for surgery and the best time to perform surgery is often difficult to determine. In addition, these patients often have unrealistic expectations about the risk/benefit ratio of surgery. Thus, it is recommended that for patients with persistent severe pain and disabling functional impairment, decisions regarding surgery for LSS should be based on a shared decision-making approach. Shared decision making involves providing patients with the knowledge needed to make an informed decision and ensuring that the decision reflects the patient’s preferences and values in terms of what matters most to the patient (e.g. pain, function, risk, etc...). For patients with LSS, key knowledge would include the moderate benefit associated with surgery that may diminish over time, the likelihood of improvement with or without surgery and the potential risk and costs. Shared decision-making video program have been shown to improve the patient’s knowledge and influence treatment decisions regarding spine surgery.

Regional musculoskeletal pain syndromes

Mihaela C. Micu, Ruxandra E. Schiotis, Ingrid Möller, Esperanza Naredo

A previous version was coauthored by Cathy Speed, Esperanza Naredo, Ingrid Möller

LEARNING OBJECTIVES

- ➔ To list and describe the spectrum of conditions that can present as regional musculoskeletal pain
- ➔ To outline the classification of regional musculoskeletal pain syndromes
- ➔ To describe and explain the anatomical basis of regional musculoskeletal conditions
- ➔ To evaluate the individual with regional musculoskeletal pain by obtaining an appropriate history, examination and investigation approaches
- ➔ To make adequate decisions about additional diagnostic procedures (mainly diagnostic imaging)
- ➔ To describe and explain the diagnostic capabilities and advantages of musculoskeletal ultrasound, over physical examination, in regional musculoskeletal conditions
- ➔ To educate patients about the expected course of their symptoms, and factors that might influence prognosis
- ➔ To manage these disorders

1 Introduction

Pain at regional sites, such as the shoulder, knee, lateral elbow, heel or trochanter, is the most common form of musculoskeletal complaint encountered by clinicians in musculoskeletal practice. Most of these complaints are due to soft tissue disorders, and these will form the focus of this chapter. Complex regional pain syndromes (CRPS) are also described here.

This chapter starts with a general overview of the classification of regional musculoskeletal complaints and their epidemiology. The importance of a thorough knowledge of functional anatomy in understanding many of these conditions and their clinical assessment (history, examination and investigation) and management is emphasised. The role of musculoskeletal ultrasound in the diagnosis and local management of the above disorders is also described.

Finally, common specific regional pain syndromes are discussed and interactive cases will help to provide a more in-depth view of two selected conditions.

2 Definition, classification, aetiology and pathogenesis

Regional musculoskeletal pain syndromes (MPS) are disorders of tendons, ligaments, bursae, joint capsules, fasciae, muscles and peripheral nerve entrapments in one or more regions of the body. The presenting symptom is typically pain, arising from soft tissue owing to underlying structural pathology, pain in soft tissues without underlying structural pathology or more diffuse pain syndromes such as CRPS.

Clear, concise and universally accepted terminology in the description and classification of regional MPS is important. Much of the confusion in terminology relates to the many complexities in disorders of the soft tissues, the lack of a true anatomical basis, the lack of evidence for validity and reliability of most classification systems, and the difficulty in establishing a clear diagnosis by clinical assessment. However, with advances in understanding of pain pathways and imaging techniques, our insight into the diagnosis and treatment of these conditions is improving. The implementation of musculoskeletal ultrasound in rheumatological practice leads towards the objective classification of specific disorders, and should be considered as the 'rheumatologist's stethoscope'.

2.1 Classification systems for regional MPS

Classification of regional MPS can be as follows;

2.1.1 Underlying pathology

1. Pain with underlying structural lesions; tendon, ligament, muscle disorders, bursal pathology, enthesopathy, neurovascular entrapment (carpal, tarsal, cubital tunnel syndrome, thoracic outlet syndrome).
2. Pain without underlying structural pathology: referred pain, myofascial syndrome.
3. Complex regional pain syndromes (CRPS type I, type II).

2.1.2 Pain: regional site, and duration

1. Regional site of pain: shoulder, elbow, wrist, hand, hip, knee, ankle, etc.
2. Duration: <2 weeks (acute), 2–12 weeks (subacute) and >12 weeks (chronic)

2.2 Aetiology and pathogenesis of soft tissue lesions

Information on the aetiology of the symptoms helps to classify the complaint and also to manage it.

Local and systemic risk factors predisposing to soft tissue lesions are presented in boxes 1 and 2. In some patients, however, no explicit cause can be identified.

Box 1 Aetiological or risk factors in soft tissue lesions

Intrinsic

- Strength and proprioception decline with age
- Biomechanical malalignments
- Muscle imbalance
- Hypermobility/hypomobility (localised or general)
- Impaired vascularity/innervation
- Fatigued muscles (altered movement patterns)

Extrinsic

- Poor equipment
- High musculoskeletal demand—musculoskeletal overuse
- Inadequate training patterns (volume, content, intensity, timing)
- Trauma
- Environment (e.g., extremes of temperature)
- Drugs (see box 2)

Others

- Immobilisation (tissue atrophy, weakness)
- Local steroid injection
- NSAIDs (can mask injury)

NSAIDs, non-steroidal anti-inflammatory drugs.

Box 2 Systemic disorders and drugs associated with soft tissue disorders

- Inflammatory and crystal arthropathies
- Any joint pathology which may alter biomechanics
- Diabetes mellitus
- Oestrogen deficiency (including menopause)
- Drugs: glucocorticoids, fluoroquinolone antibiotics, anabolic steroids.
- Possibly, stress and overtraining: increased circulating glucocorticoids and catecholamine

2.3 Myofascial syndrome

Regional myofascial pain syndrome presents with muscle pain in a specific region of the body. Exertion of pressure on sensitive points in the muscles trigger points (TPs) causes pain in seemingly unrelated parts of the body (referred pain). It can be associated with a number of other sensory, motor or autonomic phenomena (Cummings and Baldry, 2007).

2.4 Complex regional pain syndromes

Reflex sympathetic dystrophy and causalgia were changed and renamed (1994) as CRPS according to the type of inciting event (CRPS type I and II), rather than by any differences in the clinical presentation or pathophysiology. The modified diagnostic criteria, mentioned above, produced better discrimination between CRPS and non-CRPS neuropathic pain (Harden et al, 1999; Harden et al, 2007).

CRPS type I is characterised by the presence of an initiating noxious event or a cause of immobilisation. CRPS type II is characterised by the presence of a defined nerve injury. Both, types I and II have the following characteristics:

1. Continuing pain, allodynia or hyperalgesia disproportionate to the inciting event.
2. Evidence of oedema, changes in skin blood flow or abnormal sudomotor activity in the painful region at some point during the evolution (figure 1).
3. The diagnosis excludes conditions that would otherwise account for the degree of pain and dysfunction.

Figure 1 Complex regional pain syndrome. (Source: Cofer, <http://www.lecofer.org>)

Note: Criteria 1, 2 and 3 are necessary for a diagnosis of complex regional pain syndrome.

3 Clinical principles and paraclinical examinations

3.1 History

Assessment starts with taking a careful history, usually a pain history (site, radiation, character- mechanic/ inflammatory, time and mode of onset, aggravating factors, associated symptoms, functional limitation). A further history is obtained, noting past medical history, previous episodes of pain, management to date, presence of other pain problems, hand dominance, occupation, sports and hobbies. This information may help to establish a diagnosis, and to estimate the prognosis of the pain problem. A systemic enquiry is also important, as regional pain may be due to an underlying medical condition (e.g., neoplasm or inflammatory arthritis).

3.2 Examination

Clinical examination of a regional musculoskeletal complaint involves specific steps: inspection, palpation (areas of tenderness), movement assessment by specific testing). Remember that examination is not restricted to the site of pain—for example, upper limb pain syndromes may be referred from the neck. The examination is completed by performing a general medical examination including neurovascular status.

3.3 Investigation

In some patients, further investigation, guided by the clinical picture is necessary to clarify the diagnosis and/or take the appropriate therapeutic decision. This may involve blood tests if an underlying systemic disease is suspected. However, in most cases investigation will involve imaging—in particular, diagnostic ultrasound. Plain radiography, magnetic resonance imaging (MRI), computed tomography (CT) and nuclear medicine techniques may be alternative imaging modalities in a few patients when a thorough history and examination do not provide sufficient diagnostic information.

3.3.1 Diagnostic musculoskeletal ultrasound

Over the past decade, high-resolution, high-frequency musculoskeletal ultrasonography has been progressively incorporated into rheumatology practice. This imaging modality provides valuable real-time morphological and functional information about musculoskeletal structures (figure 2).

Figure 2 Panoramic ultrasound image of the elbow and forearm in longitudinal plane. The humeroradial joint and different muscles are visualised. bch, brachialis muscle; bchr, brachioradialis muscle; hc, humeral condyle; rh, radial head; sp, supinator muscle.

Musculoskeletal ultrasound performed at the time of the consultation allows for an immediate correlation between imaging findings and clinical data, which can greatly enhance diagnosis capability and improve management of patients with soft tissue disorders (Micu et al, 2013). The principal applications of ultrasonography in soft tissue disorders are summarised in box 3. Power and colour Doppler enables assessment of blood flow in soft tissue lesions. However, its value is extremely user-dependent and the user must have a solid knowledge of functional anatomy, scanning technique, normal sonoanatomy and pathological findings.

Box 3 Applications of musculoskeletal ultrasonography in soft tissue disorders**1. Tendon lesions**

- 1.1 Differential diagnosis between tendinosis, tenosynovitis/paratenonitis, enthesopathy, tear and subluxation
- 1.2 Evaluation of extension and size of tendon tears
- 1.3 Detection of tendon calcification and microcrystal deposits
- 1.4 Assessment of tendon function

2. Bursitis

- 2.1 Detection of bursitis, including some that are neither visible nor palpable by clinical examination
- 2.2 Differential diagnosis between bursitis, cellulitis and arthritis

3. Ligament lesions

- 3.1 Diagnosis of acute and chronic ligament rupture (medial collateral ligament at the knee, lateral ligaments at the elbow and ankle)

4. Muscle lesions

- 4.1 Detection of muscle ruptures
- 4.2 Evaluation of extension and size of muscle ruptures
- 4.3 Assessment of muscle function
- 4.4 Monitoring of healing process of muscle ruptures
- 4.5 Detection of ossificant myositis

5. Peripheral nerve entrapments

- 5.1 Diagnosis of nerve compression at osteofibrous tunnels
- 5.2 Detection of local causes of peripheral nerve entrapment
- 5.3 Diagnosis of some superficial neurogenic tumours (Morton's neuroma, schwannomas)

6. Ganglia and cysts

- 6.1 Diagnosis of ganglia and assessment of their size and relation with neighbouring structures

7. Subcutaneous masses

- 7.1 Differentiation between solid or liquid nature

8. Guidance of perilesional and intralesional musculoskeletal injections**3.3.2 MRI**

MRI has the advantage over ultrasound of allowing imaging of any anatomical structure or location (particularly bone marrow, which is not visible on ultrasound). It provides excellent multiplanar imaging of all anatomical structures and T1- and T2-weighted images, and fat-suppressed and proton-dense views provide information about bone oedema, blood or water content and muscle atrophy. MRI is helpful in the differential diagnosis of some disorders such as meniscal lesions or malignant lesions in soft tissues or bones as well as in the management of recalcitrant soft tissue complaints that can lead to clinical misdiagnoses. The disadvantages of MRI are its cost and limitations of accessibility.

3.3.3 CT

CT involves exposure to radiation and is reserved for defining details of bony anatomy that may contribute to soft tissue pain—for example, subtle osteophyte formation, when MRI has been insensitive or when contraindicated. Otherwise it has few advantages over MRI.

3.3.4 MRI or CT arthrography

MRI or CT arthrography are useful for the identification of labral and capsular pathologies in the shoulder.

3.3.5 Plain radiography

Radiography need not be performed routinely but allows confirmation or can help to exclude bony pathology (e.g., ruling out glenohumeral osteoarthritis in painful shoulder).

Radiographs also allow identification of any anatomical features that may be contributing to the injury or condition (e.g., an acromial spur in rotator cuff tendinopathy contributing to subacromial impingement, tendon calcifications, or a Haglund's deformity in retrocalcaneal bursitis and Achilles tendinitis).

3.3.6 Radionuclide imaging

Radionuclide imaging (bone scans) can be useful to exclude osseous or joint pathology. Triple phase bone scans are used in the assessment of CRPS.

3.3.7 Electrophysiological studies

Electrophysiological studies (i.e., nerve conduction and electromyography) can be useful for confirming the diagnosis of clinically suspected peripheral nerve entrapments and evaluating their severity.

3.3.8 Positron emission tomography (PET)

PET is a nuclear medicine functional imaging technique feasible for studying skeletal muscles (superficial and deep) during exercises. No studies have examined applications of PET or single-photon emission CT for regional pain syndromes.

4 Principles of management

Although there is limited high-quality evidence for the efficacy or effectiveness of many interventions, several general principles can be followed in the management of patients with regional MPS. The underlying principle of management of most regional musculoskeletal complaints is to control pain so that rehabilitation can proceed. Rehabilitation is a customised process, which aims to achieve an optimal functional outcome. In addition, providing information to the patient about the nature of the condition, beneficial and negative habits

and activities, self-help exercises, expected response to treatment and outcome should all be part of the approach to these patients.

4.1 Exercise

Relative rest, active rehabilitation and a gradual return to tendon-loading activities are key points in successful treatment of soft tissue disorders. Progressive exercise is a fundamental part of the treatment of most regional musculoskeletal complaints (Cummings and Baldry, 2007). An exercise programme can be designed and supervised by well-trained physiotherapists and can be started early, initially with postures and active isometric muscle contractions (against resistance, without joint movement) in the acute injury, in order to achieve a functional recovery and prevent further injury. The goal should be to work towards full, specific, pain-free functional activity. All activity should be followed by further flexibility exercises. Aquatic treatment, when possible, should be part of the rehabilitation strategy as it promotes non-weight bearing movements of the affected anatomical region.

In myofascial pain syndromes, a review of postural problems and ergonomics should be carried out. The aim in these conditions is to reduce the neural sensitisation that is considered to drive much of the pain.

Proprioceptive training is important in some conditions, such as ankle sprains and rotator cuff complaints. Muscle imbalances, which are common and yet overlooked, must be assessed and considered when designing an exercise programme.

4.2 Pain management

Non-pharmacological and/or pharmacological approaches to pain management can be used.

4.2.1 Non-pharmacological approaches

The most frequently used modality in acute soft tissue injuries is ice, which has anti-inflammatory and analgesic actions.

Therapeutic ultrasound is used in soft tissue injuries, although there is no good evidence to support its use (Speed, 2001). It increases soft tissue extensibility, decrease tissue stiffness and muscle spasm, increase blood flow and modulate pain. Some experimental evidence suggests that ultrasound may speed resolution of inflammation, accelerate fibroblast function, accelerate angiogenesis and increase matrix synthesis and the strength of healing tissues.

Laser therapy has effects similar to those of ultrasound. It decreases inflammation and may be useful in superficial injuries.

Extracorporeal shock wave therapy (ESWT) is used in the treatment of insertional tendon lesions (enthesopathies). Animal model studies have indicated that its effects include tissue repair, reduction of nociceptors and reduction of calcification. Evidence supports the use of focused ESWT in calcific tendinopathies (Speed, 2014).

Acupuncture and transcutaneous electrical nerve stimulation (TENS) may also be helpful in the management of pain, particularly that resulting from chronic soft tissue injuries (Johnson and Martinson, 2007).

Resting splints, used intermittently, are often useful for the prevention of soft tissue shortening while healing is taking place (e.g., in plantar fasciitis and Achilles tendinosis). They can also stop excessive movement.

4.2.2 Pharmacotherapy

When intervention with medication is considered necessary in the management of regional pain, analgesic therapy or non-steroidal anti-inflammatory drugs (NSAIDs) may be an alternative as first choice. Those patients with night pain who do not respond to these treatment alternatives may benefit from short-term supplementation with an opioid compound (synergistic effect). (e.g., Green et al, 2002; Speed, 2005).

The potentially significant side effects of NSAIDs are many and varied, including gastrointestinal effects (less marked with cyclo-oxygenase 2 selective drugs) and thrombotic cardiovascular effects. The results of some small randomised trials support the use of topical NSAID gel or iontophoresis for short-term pain control, without systemic side effects (Mazières et al, 2005).

Other more potent drugs that may be useful in the management of regional pain include regular basic analgesics, tricyclic agents, gabapentin and pregabalin, which are used mostly where there is significant neuropathic pain. Although considered standard approaches in this situation, evidence for efficacy is lacking and side effects are a concern. Antibiotics are indicated when a soft tissue infection is confirmed.

4.3 Injection therapies

4.3.1 General approach

Local injection therapies are commonly used for soft tissue disorders and include a spectrum of injectates. Again, strong evidence is lacking for their use in most musculoskeletal complaints.

Classic routes and injectates for local injection therapies in soft tissue complaints are listed in box 4. The choice of injectate depends upon the specific characteristics of the condition. Those most commonly used include glucocorticoid for its anti-inflammatory properties and pain control, local anaesthetic (LA), particularly for diagnostic purposes, sclerosants for pain management, dry needling and platelet-rich plasma to promote healing, botulinum for muscle pain, and nerve blockades for general pain relief regionally.

Musculoskeletal injections are often performed using external anatomical landmarks ('blind' injections). Some studies have reported a variable accuracy of palpation-guided needle placement in extra-articular and intra-articular injections and higher incidental damage of adjacent non-target structures in comparison with ultrasound-guided interventional manoeuvres (Slawsky et al, 2011).

Ultrasound is a valuable tool for guiding accurate and safe musculoskeletal perilesional or intralesional injections. At the same time, this technique provides confirmation of the clinical diagnosis and the indication for injection. Real-time ultrasound enables accurate needle placement. Drug delivery can be visualised during and after the procedure (figures 3 and 4, video 1 and 2). Injections into anatomical structures adjacent to the intended target (e.g., vessels, nerves, subcutaneous fat) can be avoided because they are easily identified by ultrasound.

Video 1. Real time video for corticosteroid injection inside the subacromial subdeltoid bursa Transverse scanning of the supraspinatus tendon. The needle is penetrating (free hand injection, 'in plane' technique) the skin, subcutaneous tissue, deltoid muscle and superficial SASDb wall. CS deposition is made strictly inside the bursa. (You must be connected to internet and use Acrobat reader to see the video. Another version is available in the "images" section of the course)

Video 2. Postprocedural hyperechoic (white) corticosteroid deposition strictly inside the subacromial subdeltoid. Longitudinal scanning of the supraspinatus tendon. (You must be connected to internet and use Acrobat reader to see the video. Another version is available in the "images" section of the course)

Box 4 Routes and materials for regional musculoskeletal pain

Routes

- Intra-articular (capsulitis)
- Intrasheath (tenosynovitis)
- Intrabursal (bursitis)
- Intratendinous (sclerosant treatment for pathological neovascularisation, autologous blood, platelet-rich plasma, dry needling)
- Local infiltration (carpal tunnel, trigger point, ligament, muscle)
- Peripheral nerve blockade (perineural injection)

Materials

- None (dry needling)
- Local anaesthetic
- Glucocorticoids (with/without local anaesthetic)
- Viscosupplementation agents (joint pain)
- Sclerosants
- Platelet-rich plasma
- Botulinum toxins
- Heparin
- Prolotherapy (dextrose and lidocain)

Figure 3 Glucocorticoid deposition (hyperechoic spots, long arrow) inside the subacromial-subdeltoid bursa during injection. The needle (short arrow) is visualised as hyperechoic. DM, deltoid muscle; SST, supraspinatus muscle tendon.

Figure 4 Glucocorticoid deposition (hyperechoic spots, long arrow) inside the subacromial-subdeltoid bursa after injection. DM, deltoid muscle; SST, supraspinatus muscle tendon.

Although the impact of accurate needle placement in the therapeutic response to local glucocorticoid injection reported in the literature needs further elucidation (Naredo et al, 2004), injection accuracy is significantly higher when imaging is used to guide musculoskeletal injections than with landmark-guided traditional injections (Daley et al, 2011).

4.3.2 LA injections

Injections of LA alone are used for both diagnostic and therapeutic purposes in soft tissue conditions. In the patient with myofascial pain, local injection of a TP with anaesthetic aims to mechanically disrupt it and, where LA is used, desensitise the area. Reduction of pain then allows a stretching and exercise programme, to increase the range of motion, and to improve exercise tolerance.

4.3.3 Glucocorticoid injections

Most local glucocorticoid injections for soft tissue disorders are extra-articular, and are either delivered around the lesion (e.g., peritendinous or tendon sheath infiltration), or into the lesion itself, (e.g., intrabursal injection). Steroid injections are also used for diagnostic and therapeutic nerve blockades. Contraindications and unwanted effects of local glucocorticoid injections are listed in box 5.

Box 5 Contraindications and unwanted effects of local glucocorticoid injections in soft tissue lesions

Contraindications

- Local or systemic infection
- Coagulopathy
- Tendon tear

Potentially unwanted effects of local glucocorticoid injections

- Hypersensitivity—local or systemic
- Tissue atrophy
- Tendon rupture
- Infection—local or systemic
- Post injection ‘flare’ of symptoms
- Osteonecrosis/steroid arthropathy (intra-articular injections, weight bearing joints)
- Facial flushes
- Abnormal menstrual bleeding

Some suggestions for the practical application of local glucocorticoid injections are given in box 6. Intra-articular injections for soft tissue conditions include those used for capsulitis, with or without hydro distension of the joint.

Box 6 Suggestions for practice when using local glucocorticoid injections

- Informed consent should be obtained from the patient, who must be willing to follow post injection guidelines
- The practitioner should have full knowledge of the local anatomy
- Select the finest needle that will reach the lesion according to the injected drug
- The practitioner's hands and the patient's skin should be cleansed and a no-touch technique used
- Use short-/medium-acting glucocorticoid preparations in most cases, with local anaesthetic
- Injection should be peritendinous; avoid injection into tendon substance
- A minimum interval should be respected between injections (e.g., 3–6 weeks)
- Use a maximum of three injections at one site. However, it depends on the anatomical area, interval between injections and previous response
- Soluble preparations may be useful in those patients who have had hypersensitivity/local reaction to previous injection
- Details of the injection should be carefully recorded
- Do not repeat if two injections do not provide at least 4 weeks' relief
- Warn the patient of early post injection local anaesthesia, to avoid initial overuse
- The patient should inform the doctor if there is any suggestion of infection or other significant adverse event
- Use ultrasound guidance if available, especially for complex anatomical areas

4.3.4 Botulinum toxins

Botulinum toxins block the presynaptic release of the neurotransmitter acetylcholine in a number of painful conditions, including myofascial pain, muscular low back pain, spasticity, headache and other neurological disorders.

4.3.5 Others

Low-dose heparin has been used in the management of acute Achilles paratenonitis on the basis of limiting the formation of adhesions. However, there is some evidence showing no beneficial effect and it has been suggested that heparin may, itself, cause a degenerative tendinopathy.

Hyaluronic acid injection has also been proposed as an approach in the management of soft tissue mediated pain. Some promising results have been seen in the treatment of tendinopathies. The positive effect relies on its anti-inflammatory activity, enhanced cell proliferation and collagen deposition and lubricating action (Abate et al, 2014).

Subacromial injection of anakinra, has been proposed for the management of rotator cuff tendinopathy and subacromial bursitis. However, no randomised controlled trials (RCTs) have been performed.

Other injection techniques that are sometimes used in chronic conditions include autologous blood injections and sclerosant treatments, but the evidence for these is limited (Hoksrud and Bahr, 2011; Burke CJ et al, 2016).

Platelet-rich plasma (PRP) injections may help in tendon healing by modifying their intrinsic reparative capacity (Dragoo et al, 2014; Lhee SH and Park JY, 2013; Gosens T et al, 2012; Zhang JY et al, 2016)..

4.4 Surgery

Surgery is usually avoidable for soft tissue disorders, but can be considered under some circumstances (box 7).

Box 7 Indications for surgery in soft tissue conditions

Assessment

- Arthroscopic assessment of soft tissue disorders related to joint pathology

Repair of structures

- To repair total rupture of a structure, such as the Achilles tendon or the rotator cuff
- To repair tears within the tendon substance that have failed to heal and continue to prevent a positive response to conservative management

Excision of degenerate lesions or partial tears

- To resect mucoid degeneration in patellar or elbow common extensor tendon tendinopathy

Release of structures (if strongly impairing function)

- To release tight or scarred structures (e.g., adhesive capsulitis)
- To release an area of stenosis surrounding a tendon (e.g., stenosing tenosynovitis) or a peripheral nerve (e.g., carpal tunnel syndrome)

Alteration of contributing anatomical structures

- On failure of conservative management in a tendinopathy where there is a precipitating mechanical cause, such as Haglund's deformity in retrocalcaneal bursitis (see below)

Instability

- Continuing mechanical and functional instability of a joint such as shoulder dislocation, especially in young people

Inadequate response to conservative treatment—persistent pain and functional impairment

5 Common regional MPS

This section describes the diagnosis and management of several regional musculoskeletal pain problems in more detail. It is certainly not exhaustive, but covers several important regional pain syndromes found in rheumatology practice. At the end of this chapter suggestions are given for further reading on MPS.

In clinical practice we rely on proposed guidelines or protocols and stratify our therapeutic options according to a certain identified pathology. Ultrasound evaluation performed immediately after clinical examination may deliver new information about the underlying pathology, may change the clinical diagnosis and lead to a change in the therapeutic strategy (Micu et al, 2013).

5.1 The shoulder

5.1.1 Epidemiology and risk factors

Shoulder complaints cause significant pain and disability in the general population and place a major burden on the economy owing to the cost of healthcare, lost earnings and social security payments. Shoulder pain has a point prevalence of 7–21% of adults in the community and is the second most common musculoskeletal complaint presenting to primary care, with only back pain presenting more often (Killian et al, 2012).

Most shoulder complaints are due to soft tissue lesions, with chronic degenerative rotator cuff disorders being the most common group. The origin of many shoulder complaints is multifactorial and articular and extra-articular disorders can coexist. Repetitive work or sport overhead activity are considered the major risk factors for rotator cuff lesions. Other risk factors include old age, shoulder anatomical variants and glenohumeral instability or hypermobility in young people (Killian et al, 2012).

5.1.2 Clinical anatomy

The functional anatomy of the shoulder is complex, probably because it has the greatest mobility among all joints in the body. The shoulder girdle is composed of four articular surfaces (i.e., sternoclavicular, acromioclavicular, glenohumeral, and scapulothoracic). Surrounding muscles and ligaments provide stability to the glenohumeral joint. Among them, the rotator cuff (RC) is the primary dynamic stabiliser by compressing the humeral head in the glenoid fossa during shoulder abduction. The RC is composed of four muscles (i.e., supraspinatus, infraspinatus, subscapularis and teres minor) that form a cuff around the head of the humerus, to which these muscles attach (figures 5A, B).

The biceps muscle is made up of a long and a short head, each of which has different proximal tendon origin, and shares a distal attachment at the radial tuberosity and the ulna. The coracohumeral and the transverse humeral ligament (an extension of the subscapularis tendon) maintain the biceps tendon into the bicipital groove.

The large subacromial–subdeltoid bursa covers the rotator cuff and lubricates and protects these tendons from the pressure and friction of the under surface of the acromion.

The principal actions attributed to the rotator cuff muscles are humerus abduction by the supraspinatus (along with the deltoid muscle), external rotation by the infraspinatus primarily and teres minor, and internal rotation by the subscapularis. The pectoralis major, latissimus dorsi and teres major also assist in internal rotation. The action of the biceps brachii muscle is supination and flexion of the forearm.

Figure 5 (A) Rotator cuff. 1, supraspinatus muscle; 2, infraspinatus muscle; 3, teres minor muscle; 4, greater tuberosity; 5, spine of the scapula; 6, humeral shaft. **(B) Rotator cuff and subacromial space.** 1, subscapularis muscle; 2, supraspinatus muscle; 3, infraspinatus muscle; 4, teres minor muscle; 5, coracohumeral ligament. 5.1.3 Main causes of shoulder pain

The main causes of shoulder pain are outlined in table 1. Most patients with shoulder pain have lesions involving the RC tendons, particularly the supraspinatus tendon. RC impingement is considered the initial stage of tendinosis and tear in most patients with painful shoulder syndrome. In clinical practice and on imaging (i.e., ultrasound, MRI), these disorders are often found to overlap in the same patient.

5.1.4 Pathogenesis of shoulder tendinopathy

The pathogenesis of tendon disorders in painful shoulder syndrome remains unclear. Histopathological studies have described a degenerative process of the tendon with little evidence of inflammation, which may play a role only in the early stages of the pathogenic process (Rees et al, 2006; Dean et al, 2013). Because inflammatory changes are seldom present, the terms ‘tendinosis’ or ‘tendinopathy’ may be more appropriate than ‘tendinitis’.

Intrinsic (i.e., tendon degeneration due to overuse and ageing, microvascular insult) and extrinsic factors (i.e., compression of the rotator cuff by surrounding structures such as the acromion, the coracoacromial ligament and/or the coracoid process) (figure 6) have been involved in the pathophysiology of rotator cuff disorders.

Table 1 Main causes of shoulder pain

Site	Lesions
Rotator cuff (associated lesions commonly found)	Impingement Tendinosis Tear (partial-thickness, full-thickness, complete) Calcifying tendinopathy
Tendon of long head of biceps	Tendinopathy and tenosynovitis Tear (partial, complete) Subluxation/dislocation
Bursae	Subacromial–subdeltoid bursitis Other bursitis
Capsule	Adhesive capsulitis
Joint complex	Capsulolabral lesions
Joints	Glenohumeral osteoarthritis Acromioclavicular osteoarthritis, dislocation
Nerves	Lesions of cervical roots, brachial plexus or peripheral nerves, thoracic outlet syndrome
Muscle	Myofascial pain syndromes
Others	Local bone or muscle destructive lesions
Referred pain	Cervical spine, intrathoracic tumours, ischaemic heart disease, hepatic and gallbladder diseases

5.1.5 Diagnosis of shoulder pain

The first step in the diagnosis process of non-traumatic shoulder pain should be differentiation between intrinsic causes and referred symptoms caused by disorders extrinsic to the shoulder. Unlike intrinsic shoulder pain, referred pain usually is neither caused nor affected by shoulder movements.

Intrinsic shoulder pain may arise from the intra-articular or the periarticular structures. A careful clinical history and physical examination are useful to distinguish both groups of disorders. However, they can coexist in the same patient. In addition, degenerative periarticular lesions, which frequently overlap, are difficult to distinguish by clinical assessment. In contrast, imaging modalities like ultrasound and MRI are very accurate in the differential diagnosis of most shoulder disorders.

5.1.5.1 History

The primary symptom is pain. A careful history of the shoulder pain should be obtained.

The *onset* of most shoulder symptoms is insidious and may be associated with repetitive microtrauma (overuse).

The *site* of the pain is a relatively useful indication of its source. Pain secondary to RC disease, glenohumeral joint and capsular disorders have similar distributions (mainly shoulder and lateral aspect of the arm). Acromioclavicular and sternoclavicular pain are usually well localised in the joint.

Exacerbating and relieving features are also noted. Pain with activities involving overhead work is suggestive of subacromial impingement or acromioclavicular joint problems. Pain which is unaffected by movement is often due to referred pain from extrinsic pathologies.

Clicking and clunking are symptoms of labral lesions and of instabilities which, in the case of the acromioclavicular and sternoclavicular joints, are well localised compared with the more diffuse symptoms when the glenohumeral joint is involved.

Weakness may be reported, which may be true weakness, pain inhibition or mechanical restriction. True weakness can result from a complete disruption of the rotator cuff tear. Neurological lesions may also cause weakness.

Nerve entrapments typically present with pain, paraesthesia and weakness distal to the site of entrapment.

Swelling of the shoulder region can occur in relation to subacromial–subdeltoid bursitis (most common) or arthritis (acromioclavicular, glenohumeral).

Enquiry about the presence of *systemic symptoms* is mandatory. Symptoms such as fever, weight loss and anorexia may suggest infection, malignancy, inflammatory arthritis or polymyalgia rheumatica.

The degree of *functional disability* may be assessed informally by determining the types and degree of activities affected and the number of days lost from work/play, or by a formal evaluation.

5.1.5.2 Physical examination

Examination of the patient starts with inspection and palpation of the region (site of tenderness, crepitus, temperature). Evaluation of movement starts with inspection of the range, comfort and rhythm of movement while the patient performs active movements in all planes. A painful arc of abduction in mid-range is typical of subacromial pathology, and the pain is often eased with supination of the arm, which decreases impingement. A superior painful arc is found with acromioclavicular pathologies—in particular, osteoarthritis. RC tendinosis and partial-thickness tears are often difficult to distinguish as both may cause pain with little or no loss of motion. Active range of movement can be compared with that of passive movement. Restriction of both is indicative of glenohumeral joint or capsular pathology, whereas good passive range of motion in the presence of active restriction indicates either a musculotendinous or neurological injury.

There are some simple active manoeuvres that provide quick information about the main shoulder movements.

Specific active movements are tested against resistance provided by the examiner, who notes the presence of pain and weakness and whether the latter is out of proportion to the pain. Some of the manoeuvres most used to detect RC and biceps tendon involvement are listed in table 2. These tests are positive when they elicit the pain usually experienced by the patient. In addition, the patient's inability to resist the examiner's pressure may indicate tendon rupture.

Overall, physical examination techniques for RC pathology show moderate sensitivity for the presence of some lesions and low specificity for the distinction of specific tendon involvement and lesions (Naredo et al, 2002*; Lasbleiz et al, 2014), (figures 7 and 8).

The *cervical spine* should also be assessed since it is a common source of shoulder pain. This includes evaluation of range of movement and the surrounding musculature. A full general examination and neurovascular assessment of the upper limbs should also be performed.

Table 2 Principal clinical manoeuvres used to detect rotator cuff and biceps tendon involvement in shoulder pain syndrome

Clinical tests and description	Tested tendon
Impingement manoeuvres of Neer: the examiner stands behind the seated patient and uses one hand to prevent rotation of the scapula while passively raising the patient's arm with the other hand to produce both forward elevation and abduction in order to reduce the space between the greater tuberosity and the anteroinferior aspect of the acromion	Coracoacromial rotator cuff impingement
Hawkins's test: the examiner stands facing the patient, and, after raising the patient's arm to 90° of strict forward elevation with the elbow in 90° flexion, rotates the arm medially by lowering the forearm	Coracoacromial rotator cuff impingement
Yocum's test: the patient is asked to place the hand on his or her other shoulder and to raise the elbow without raising the shoulder	Coracoacromial rotator cuff impingement
Jobe's manoeuvre: the examiner stands facing the patient, who places both arms in 90° abduction and 30° horizontal adduction, in the plane of the scapula, with his thumbs pointing downward in order to produce medial rotation of the shoulder; the examiner then pushes the patient's arms downward while asking the patient to resist the pressure	Supraspinatus tendon
Patte's manoeuvre: the examiner supports the patient's elbow in 90° of forward elevation in the plane of the scapula with the elbow in 90° flexion while the patient is asked to rotate the arm laterally in order to compare the strength of lateral rotation	Infraspinatus tendon
Gerber's lift off test: the patient is asked to place the hand against the back at the level of the waist with the elbow in 90° flexion. The examiner pulls the hand to about 5–10 cm from the back while maintaining the 90° bend in the elbow. The patient is then asked to hold the position without the examiner's help	Subscapularis tendon
Yergason's test: resisted supination of the forearm; the patient is asked to perform a combined movement of flexion at the elbow along with medial rotation of the arm while the examiner resists	Long head of the biceps tendon
Speed's test (palm up test): the patient is asked to raise the arm anteriorly against resistance, with the elbow extended and the palm facing upward	Long head of the biceps tendon
Popeye's sign: visible prominence in the distal arm (i.e., distal displacement of the rupture biceps muscle belly)	Long head of the biceps tendon

5.1.5.3 Imaging investigation

Diagnostic imaging of the shoulder can be very useful when directed by initial clinical assessment.

Musculoskeletal ultrasound allows both morphology and functional assessment, dynamic investigations of tendon, muscles and joints, comparison with the contralateral shoulder to differentiate anatomical variants from real lesions, immediate correlation between clinical and other imaging findings at the time of consultation, and accurate and safe guidance for injections with better outcome (Tagliafico et al, 2014*). The diagnostic accuracy of ultrasound for detecting subacromial disorders has been dealt with in a systematic literature review and meta-analysis. The results showed a high accuracy of ultrasound for detecting rotator

cuff tears, tendinosis and calcifications, and subacromial–subdeltoid bursitis (Ottenheijm et al, 2010; Ottenheijm et al, 2014). Some illustrative examples are shown in figures 9A–E.

Figure 9 (A) Transverse ultrasound image of the supraspinatus tendon (ss) showing a full-thickness tear filled with anechoic fluid (f). (B) Longitudinal ultrasound image of the supraspinatus tendon (ss) showing a full-thickness tear filled with anechoic fluid (f). (C) Longitudinal ultrasound image of the supraspinatus tendon (ss) showing a partial-thickness tear (t) and subdeltoid bursitis (b). (D) Transverse ultrasound image of the supraspinatus tendon (ss) showing calcifications as hyperechoic foci with acoustic shadowing (c). (E) Longitudinal ultrasound image of the supraspinatus tendon (ss) showing calcifications as hyperechoic foci with acoustic shadowing (c). cp, coracoid process; dm, deltoid muscle; gt, greater tuberosity; hh, humeral head.

Plain radiography of the shoulder generally provides little useful information in non-traumatic shoulder pain. However, this classic imaging technique has considerable value in the diagnosis of fractures, glenohumeral or acromioclavicular osteoarthritis, glenohumeral dislocation and large rotator cuff calcifications.

MRI is highly accurate in the diagnosis of RC tear and bone abnormalities (avascular necrosis, tumours). It is especially valuable in the overall assessment of the rotator cuff muscles and tendons when conservative treatment fails and surgery is planned or when shoulder pathology is complex or unclear. One important limitation is that it does not allow dynamic real-time shoulder examination.

5.1.6 Management

Many treatments for soft tissue disorders of the shoulder exist, but few are supported by strong scientific evidence.

Initial conservative treatment for RC tendinopathy consists of cryotherapy (e.g., ice), relative rest (i.e., avoiding activities that aggravate symptoms, including overhead activities), and NSAIDs (Rees et al, 2006). A short course of scheduled NSAIDs (i.e., 7–10 days) may be recommended by some during the acute symptomatic phase. Thereafter, patients may use NSAIDs occasionally for analgesia if they find the medication effective (Rees et al, 2006; Van der Sande et al, 2013).

Adjunct therapies may include electrical stimulation, phonophoresis and iontophoresis, therapeutic ultrasound, laser and suprascapular nerve blockade.

Physical therapy is used to rehabilitate patients with RC tendinopathy even though there are few well-performed clinical trials of this treatment (active and passive range-of-motion exercises, stretching and strengthening of the muscles of the rotator cuff). Once rehabilitation is complete, the need for home exercises to prevent recurrence and maintain fitness should be emphasised (Burbank et al, 2008).

Subacromial bursal glucocorticoid injection is a commonly used treatment for symptomatic rotator cuff disorders that do not improve after several weeks of conservative management, including physical therapy, or with severe pain that limits rehabilitation therapy. However, evidence of its benefit over NSAIDs, xylocaine or placebo is controversial (Gaujoux-Viala et al, 2009). Although there is still a paucity of clinical trials on image-guided versus landmark-guided shoulder steroid injections, ultrasound-guided injections potentially offer a significantly greater clinical improvement over blind injections in patients with shoulder pain (Naredo et al, 2004; Sage et al, 2013; Tao Wu et al 2015). In addition, ultrasound guidance has proved useful for calcification lavage (barbotage) in calcific tendinitis of the rotator cuff.

Viscosupplementation drugs periarticular injections (hyaluronic acid). Few studies have provided data about the clinical benefits and safety profile of these drugs in shoulder osteoarthritis/supraspinatus tendinosis (open-label studies) and RC lesions without complete tear (RCT) (Tagliafico et al, 2014*; Saito S et al 2010).

There are some studies providing preliminary data on the efficacy of **platelet-rich plasma** in RC lesions.

ESWT is an established treatment (level 1 evidence) for RC calcific tendinitis. However, there is insufficient evidence to support its use in non-calcific tendinopathy (Rees et al, 2006).

For adhesive capsulitis no consensus about the first choice for conservative treatment has been established. When treatment with ice, NSAIDs and glucocorticoid oral treatments fail, glucocorticoid or hyaluronic acid intra-articular injections, capsule distension with sodium chlorate, air, TENS, ultrasound and exercise programmes are used.

Surgical treatment for RC disorders (i.e., debridement, acromioplasty or rotator cuff repair) is considered if after 6–9 months of conservative treatment, patient function and symptoms fail to improve significantly or earlier in young patients with high shoulder occupational or sport demands.

5.2 The elbow

Non-articular causes of elbow pain include muscle strains, ligamentous injuries, epicondylitis, olecranon bursitis and compressive neuropathies. This section will focus on two of the elbow pathologies—lateral/medial epicondylitis and cubital tunnel syndrome.

5.2.1 Lateral and medial epicondylitis

These soft tissue disorders consist of a tendinopathy at the origin of the wrist extensor and flexor tendons, respectively, characterised by peri-epicondylar pain. Lateral epicondylitis is also known as tennis elbow and medial epicondylitis, golfer's elbow. Both conditions represent a tendinosis and/or an enthesopathy of the respective tendon groups. Hence tennis elbow is best termed 'common extensor tendinopathy' and golfer's elbow 'common flexor origin tendinopathy'.

5.2.1.1 Epidemiology and risk factors

Overuse and trauma commonly cause these conditions. Although called 'tennis elbow' or 'golfer's elbow', most cases occur in workers who do repetitive flexion–extension or pronation–supination activities. Lateral epicondylitis, more common than medial epicondylitis, has an incidence of between 1% and 3% a year in the adult general population.

5.2.1.2 Clinical anatomy

The lateral and medial epicondyles are extra-articular structures located at the distal part of the humerus.

Lesions of the extensor carpi radialis brevis tendon, which is attached to the tip of the lateral epicondyle, and (less often) of the common extensor tendon, which attaches just posterior and distal to the tip of the lateral epicondyle, causes lateral epicondylitis. Lesions of the pronator teres and flexor carpi radialis tendons, which are attached at the medial epicondyle, cause medial epicondylitis.

The ulnar and radial collateral ligaments provide stability to the elbow. The ulnar nerve passes through the cubital tunnel into the ulnar groove, which is located between the medial epicondyle and the olecranon in the posterior aspect of the elbow and bridged by the Osborne fascia (figure 10).

Figure 10 Elbow joint. Posterior view: 1, humerus; 2, olecranon; 3, medial epicondyle; 4, lateral epicondyle. (Image provided as a courtesy of Professor Maribel Miguel, Human Anatomy and Embryology Unit, Department of Pathology and Experimental Therapy, Faculty of Medicine (Bellvitge), University of Barcelona, Spain.)

5.2.1.3 Pathogenesis

Lateral and medial epicondylitis are work- and sport-related overuse lesions. The pathogenesis consists of tendinosis, usually with involvement of the enthesis, and degenerative microtears as a result of repetitive mechanical overload (figure 11).

Figure 11 Lateral epicondylitis. (eOrthopod Images provided as a courtesy of Medical Multimedia Group (MMG). Copyright MMG 2001.)

5.2.1.4 Diagnosis

5.2.1.4.1 History

The history is that of lateral or medial epicondylar pain and tenderness which may extend to proximal wrist extensor or flexor muscle masses, respectively, worse with grip and resulting in functional difficulties. Such symptoms may be acute or insidious in onset. The severity of pain can range from mild, with minimal effect on sports or work activities, to severe, with marked impairment in basic daily tasks and sleep.

5.2.1.4.2 Physical examination

In lateral epicondylitis, localised tenderness over the lateral epicondyle and proximal wrist extensor muscle mass, pain with resisted wrist extension and resisted extension of the middle finger with the elbow in full extension, and pain with passive maximal wrist flexion with the elbow in full extension are the most useful diagnostic findings.

In medial epicondylitis, physical examination shows localised tenderness over the medial epicondyle and proximal wrist flexor muscle mass, pain with resisted wrist flexion with the elbow in full extension and pain with passive maximal wrist extension with the elbow in full extension (figure 12).

Figure 12 Palpating the insertion of the extensors of the wrist and hand, just below the lateral epicondyle. (Courtesy of Professor J A P Da Silva. Reproduced with permission from da Silva and Woolf. *Rheumatology In Practice*, Springer, 2010*.)

5.2.1.4.3 Differential diagnosis

Box 8 presents conditions that must be considered in the differential diagnosis of lateral/medial elbow pain.

Box 8 Differential diagnosis of lateral/medial elbow pain

- Lateral/medial epicondylitis
- Radial/ulnar collateral ligament lesion
- Epicondylar apophysitis (adolescents)
- Radiocapitellar bursitis
- Olecranon bursitis
- Forearm compartment syndrome
- C6 root pathology
- Radial tunnel syndrome (compression of the posterior interosseous nerve)
- Cubital tunnel syndrome (compression of the ulnar nerve)
- Radiohumeral joint pathology:
 - Synovitis
 - Osteochondritis dissecans
 - Osteochondrosis
 - Instability
- Fracture/stress fracture

5.2.1.4.4 Imaging investigation

Radiography is often unnecessary for the diagnosis and treatment of epicondylitis. MRI may demonstrate increased signal intensity of the extensor or flexor tendons close to their insertion on the epicondyles, but evidence for diagnostic performance is limited.

Ultrasound is used to identify the different elementary lesions that may be present in epicondylitis (i.e., tendinosis and/or enthesopathy, partial tears, dystrophic calcification, neovascularisation, which is likely to represent more active severe disease, and bone surface abnormalities) (figures 13A, B). This technique can be very useful to distinguish tendon involvement from other conditions causing lateral or medial elbow pain such as intra-articular synovitis, periarticular bursitis, collateral ligaments lesions and radial or ulnar nerve compression. In addition, ultrasound is helpful in guiding accurate therapeutic injections to the selected local target (e.g., peritendinous area, pathological intratendinous vascularisation, calcifications) (Radunovic et al, 2012).

Figure 13 (A) Longitudinal ultrasound image of common extensor enthesopathy with loss of normal tendon pattern and small calcifications at the enthesis. (B) Longitudinal ultrasound image of common extensor enthesopathy with loss of normal tendon pattern; hypoechoic area exhibiting Doppler sign inside the common extensor enthesis. et, extensor tendon; le, lateral epicondyle; rh, radial head.

5.2.1.5 Management

A systematic review of prospective randomised clinical trials for management of lateral epicondylitis provided a wide range of treatment options, but little evidence supporting any particular approach (Cowan et al, 2007). The treatment of epicondylitis in the more acute stages includes relative rest (R), the use of ice (I), compression (C) due to intermittent strap or counterforce braces applied distal to the bulk of the extensor mass which may reduce activity in the affected muscles, and elevation (E) (RICE treatment strategy), analgesia including acupuncture and short-term use of (preferably topical) NSAIDs. The benefit of ultrasound has not been proved but low-level laser therapy may be helpful. Local glucocorticoid injection may help with pain relief (Gaujoux-Viala et al, 2009). Other injection techniques include dry needling, PRP injection, sclerosant therapies, botulinum toxin or other therapeutic modalities such as ultrasound-guided percutaneous needle tenotomy, but the evidence is limited (Petrella et al, 2010; Tosun HB et al 2015). Extracorporeal shock wave shows mixed results in chronic cases and therefore should be reserved for recalcitrant cases where surgery is being considered.

All these approaches are used to allow rehabilitation to start. Stretching of the forearm extensor or flexor muscles and range-of-motion exercises at the elbow and wrist should start early. Progressive eccentric and isometric strengthening rehabilitation starts as soon as pain allows. Surgery should be reserved for those patients with disabling symptoms who do not respond to any of the above measures. Options include open, arthroscopic or percutaneous surgical approaches with repair of the extensor/flexor origin after excision of the torn tendon, granulation tissue and local drilling of the subchondral bone of the epicondyle, with the aim of increasing blood supply.

5.2.2 Cubital tunnel syndrome

Ulnar neuropathy at the elbow is the second most common upper extremity compressive neuropathy after the entrapment of the median nerve at the wrist (i.e., carpal tunnel syndrome). The most frequent site of focal ulnar entrapment is at the elbow, followed by the wrist (i.e., Guyon's canal syndrome).

Ulnar lesions at the elbow typically present with numbness and paraesthesia in the fourth and fifth fingers which worsen with repeated elbow or wrist flexion. Medial elbow pain with or without nocturnal awakening is common and many patients report referred pain along the medial forearm. Motor symptoms involving the intrinsic hand muscles are less common than sensory symptoms.

Clinical diagnosis of cubital tunnel syndrome is obtained from a careful history and physical examination together with knowledge of the peripheral nerve anatomy. There are a number of provocative manoeuvres for ulnar neuropathy at the elbow, including Tinel's test (i.e., tapping over the ulnar nerve at the ulnar groove), elbow flexion, pressure and combined elbow flexion with pressure. These tests are considered positive when they elicit paraesthesia or pain in ulnar-innervated regions of the hand, particularly the fourth and fifth fingers. In addition to the clinical assessment, electrophysiological studies are usually performed in ulnar neuropathy.

Ultrasound is a promising complementary diagnostic tool for cubital tunnel syndrome. An abrupt thickening of the nerve with or without abnormal echogenicity proximal to or at the ulnar groove is the principal diagnostic sign. Ultrasound can also be useful for detecting local causes of ulnar nerve compression such as bone abnormalities (e.g., spurs, deformities), ganglia or cysts, intra-articular loose bodies, muscle abnormalities and ulnar nerve cubital tunnel subluxation while performing dynamic assessment (forearm flexion).

There is a lack of studies that have prospectively tested the different conservative treatments for cubital tunnel syndrome, such as pain relief (analgesic, NSAIDs) and splints. It is generally recommended that patients should avoid keeping the elbow in a flexed position and maintaining pressure to the elbow when seated or driving.

Surgical treatment with ulnar nerve decompression or nerve transposition can be considered for patients with evidence of moderate to severe ulnar neuropathy at the elbow who have persistent or progressive symptoms beyond 6 months that are refractory to conservative treatment.

5.3 The wrist and hand

Painful soft tissue disorders of the wrist and hand such as carpal tunnel syndrome, dorsal ganglia or de Quervain's tenosynovitis, usually due to overuse, are very common in clinical practice. Occasionally, it may be difficult to differentiate overuse lesions from wrist pain resulting from a subacute injury (e.g., scaphoid fracture, triangular fibrocartilage lesion, ligament sprains, Kienböck's disease (i.e., avascular necrosis of the lunate). Radiography, ultrasound or MRI are necessary in such circumstances.

5.3.1 Clinical anatomy

The carpal tunnel (figure 14) is elliptical shaped and enclosed by the inelastic flexor retinaculum ventrally and the carpal bones dorsally. The median nerve (the most superficial structure), eight deep and superficial flexor tendons covered by synovial sheath, and the flexor pollicis longus tendon and its sheath pass through the carpal tunnel.

The dorsal wrist is divided into six extensor compartments formed by the extensor retinaculum where the extensor tendons run lined by synovial sheath (figure 15). The flexor tendons for each finger, covered by synovial sheath, travel in a fibro-osseous tunnel between the metacarpal and the distal interphalangeal joint. The superficialis tendon attaches to the middle phalanges and the profundus tendon to the distal phalanges. The tunnel provides mechanical stability by a pulley system made up of specialised ligament system (i.e., five annular pulleys and three cruciform pulleys) that anchor the flexor tendon to the bone during finger flexion.

Figure 14 Anatomical image of the distal carpal tunnel. The median nerve and flexor tendons are seen. (Image provided as a courtesy of Professor Maribel Miguel, Human Anatomy and Embryology Unit, Department of Pathology and Experimental Therapy, Faculty of Medicine (Bellvitge), University of Barcelona, Spain.)

5.3.2 Wrist tenosynovitis

5.3.2.1 De Quervain's tenosynovitis

De Quervain's tenosynovitis involves the abductor pollicis longus and extensor pollicis brevis tendons at the first wrist extensor compartment. These tendons are enclosed by a thick fibrous sheath at the level of the radial styloid process. Overuse of the thumb (e.g., repetitive gripping and grasping) leads to friction and irritation of the tendon and thickening of the fibrous tendon sheath that may progress to fibrosis and stenosing tenosynovitis.

Patients with de Quervain's tenosynovitis typically present with pain at the radial side of the wrist during grasping or thumb movements and local tenderness on the radial styloid (figure 16). Pain is aggravated by resisting thumb extension and abduction and by passively stretching the thumb tendons over the radial styloid in thumb flexion (i.e., Finkelstein's manoeuvre).

Figure 16 Palpation of the tendon sheath of the abductor pollicis longus and extensor pollicis brevis—De Quervain's tenosynovitis. (Courtesy of Professor J A P Da Silva. Reproduced with permission from da Silva and Woolf. *Rheumatology In Practice*, Springer, 2010*.)

Clinical differential diagnosis of de Quervain's tenosynovitis includes osteoarthritis of the first carpometacarpal joint (Finkelstein's manoeuvre can also be positive (figure 17), intersection syndrome, ganglia, and radial sensory nerve entrapment in the forearm (i.e., Wartenberg syndrome). Ultrasound allows us to confirm the clinical diagnosis of the above conditions and to guide accurate therapeutic injections.

Figure 17 Finkelstein's manoeuvre. Positive in De Quervain tenosynovitis. (Courtesy of Professor J A P Da Silva. Reproduced with permission from da Silva and Woolf. *Rheumatology In Practice*, Springer, 2010*.)

The treatment of de Quervain's tenosynovitis aims at reducing inflammation in the tenosynovial sheath, preventing the formation of adhesions, and preventing recurrence owing to exercises and change in hand overload. For pain relief, ice applications to the radial styloid, an appropriate splint and NSAIDs are indicated. Glucocorticoid injections, preferably guided by ultrasound to avoid inaccurate drug delivery (i.e., into the tendon instead of within the synovial sheath), can be effective especially in the acute phase (Sawaizumi et al, 2007*; McDermott JD et al, 2012) (figure 18).

Figure 18 *Transverse scanning at the first extensors compartment. Glucocorticoid injection inside the tendon sheath. The needle is visible (hyperechoic line, left). Hypoechoic material distending the tendons sheath (arrow). APL, abductor pollicis longus tendon; EPB, extensor pollicis brevis tendon; rs, cortex of the radial styloid.*

Once the symptoms of active tenosynovitis have resolved, gentle passive stretching exercises of the extensor and abductor tendons should begin. Surgery (i.e., decompression of the first extensor compartment with or without tenosynovectomy) can be indicated with persistent or recurrent symptoms despite conservative treatment.

5.3.2.2 Intersection syndrome

Intersection syndrome is caused by a conflict between the extensor carpi radialis longus and extensor carpi radialis brevis tendons (second compartment) at the intersection of the first extensor compartments, just proximal to the extensor retinaculum or between the second and third extensor compartments just distal to the extensor retinaculum. It is characterised by tenosynovitis, tendon thickening and tenosynovial adhesions. The main clinical complaint is radial wrist or forearm pain that is exacerbated by repetitive wrist flexion and extension. On physical examination, tenderness, swelling and crepitus on motion at the intersection level are the principal findings. Although much less common than de Quervain's tenosynovitis, both conditions can be

clinically confused. Ultrasound examination provides quick information about the morphology and function of these compartments (figure 19).

Figure 19 Transverse scanning of the second and third extensors compartments at the wrist level. The third compartment is just crossing the second compartment. Hypoechoic material distending the tendon sheath of the second compartment (arrows). RA, radial artery; 1, 2 extensor carpi radialis longus and brevis tendons; 3, extensor pollicis longus tendon.

5.3.3 Wrist ganglia

The wrist is one of the most common sites for ganglion cysts, which are well-delimited hard masses filled with gelatinous fluid that originate from joint capsules or tendon sheaths. Volar ganglia are less common and usually located on the lateral aspect of the wrist.

Ganglia can be painless or can cause wrist pain if they compress adjacent tendons or peripheral nerve branches. Some symptomatic ganglia are undetectable by palpation (i.e., occult ganglia). Ultrasound is an accurate imaging tool for detecting occult ganglia as well as for guiding aspiration of internal fluid and/or steroid injection into the cyst (figures 20A, B, video 3).

Video 3. Real time video for corticosteroid injection inside a radiocarpal ganglia. Longitudinal scanning of the radiocarpal joint. The needle is inserted 'out of plane' (hyperechoic dot) is penetrating inside the ganglia and drug deposition is made strictly inside the lesion. Corticosteroid deposition is presenting as a hyperechoic mass distending the ganglia. (You must be connected to internet and use Acrobat reader to see the video. Another version is available in the "images" section of the course)

5.3.4 Finger tenosynovitis

Stenosing flexor tenosynovitis, also known as trigger finger is a common condition that consists of irritation or inflammation of the fibrotenosynovial tunnel that surrounds the finger flexor tendons usually owing to overuse. The lesion leads to the formation of palpable nodules at the A1 pulley level (proximal to the metacarpophalangeal joint) which prevent the normal gliding of the tendon on motion and produce the involved finger to lock in flexion with consequent dysfunction and a variable grade of pain. In addition to overuse, diabetes mellitus is also associated with the development of trigger finger.

The diagnosis is mainly based on the clinical finding of finger locking in flexion and palpation of the typical nodule proximal to the metacarpophalangeal joint.

Treatment is based on pain relief, stretching exercises, glucocorticoid injections (video 4 and 5), (Peters-Veluthamaningal et al, 2008; Lee DH et al, 2011, Gutierrez M et al, 2016) and percutaneous or open surgical release of the A-1 pulley for persistent or recurrent cases.

Video 4. Real time video for corticosteroid injection inside the flexor pollicis longus tendon (FPLT) sheath. Transverse scanning of the FPLT shows hypoechoic halo around the tendon (tenosynovitis). The needle is penetrating 'in plane' and corticosteroid deposition (hyperechoic substance distending the tendon sheath and flowing around the tendon) is made exactly inside the tendon sheath. (You must be connected to internet and use Acrobat reader to see the video. Another version is available in the "images" section of the course)

Video 5. Postprocedural hyperechoic (white) corticosteroid deposition strictly inside the tendon sheath, with dispersion along the tendon when performing multiplanar transverse scanning of the FPLT. (You must be connected to internet and use Acrobat reader to see the video. Another version is available in the "images" section of the course)

Trigger finger should be distinguished from Dupuytren's contracture, a progressive painless fibrosis of the palmar fascia and consequent flexion contractures of the fingers. This condition is associated with work-related hand overuse, diabetes mellitus, complex regional pain syndrome, smoking, alcohol consumption and malignancy.

Figure 20 (A) Longitudinal ultrasound image of a wrist ganglion (g). (B) Transverse ultrasound image of a wrist ganglion (g). c, capitate; l, lunate; r, radius; s, scaphoid.

5.3.5 Carpal tunnel syndrome

The most common peripheral nerve entrapment is carpal tunnel syndrome. This focal neuropathy is a condition of inflammation, swelling and/or mechanical compression of the median nerve, which provides motor and sensory innervation to the hand, in the carpal tunnel of the wrist. At this site the nerve is particularly susceptible to compression, particularly with repetitive flexion–extension of the wrist and repetitive occupational use. Other causes are local trauma, swelling of tendon sheaths within the tunnel, stenosis of the tunnel by bone enlargement or fracture, thickening of the volar carpal ligament or any condition occupying the carpal tunnel. Female gender, obesity, pregnancy, menopause and hypothyroidism are also predisposing factors.

Bilateral carpal tunnel syndrome is common, although in many patients, symptoms are unilateral with subclinical involvement of the contralateral side. Symptoms are pain and paraesthesia in the distribution of the median nerve (i.e., the thumb, index, middle and radial side of the ring finger), worse at night and often wakens patients from sleep, and relieved by shaking the hand or hanging it down to the side. In chronic more severe cases there may be evidence of palmar wasting in the thenar eminence, and weakness of grip and pinch

(involvement of first and second lumbrical muscles, abductor pollicis brevis, opponens pollicis, superficial head of flexor pollicis brevis).

On physical examination, there are two classic provocative manoeuvres, the Hoffman–Tinel test (i.e., tapping over the nerve in the middle of the volar aspect of the wrist) and the Phalen test (maintained flexion of the patient's hands for 30–60 s), which are considered positive if the typical symptoms are reproduced or enhanced (figures 21A, B). However, Phalen and Tinel tests are usually inaccurate.

Figure 21 (A) Tinel's sign of the median nerve in the carpal tunnel. (B) Phalen's test. This position is kept for about 1 min: paraesthesia in the median nerve distribution suggests carpal tunnel syndrome. (Courtesy of Professor J A P Da Silva. Reproduced with permission from da Silva and Woolf, *Rheumatology In Practice*, Springer, 2010*.)

Neurophysiology studies are helpful in confirming the diagnosis and excluding other causes, such as polyneuropathy, plexopathy and radiculopathy, but may be normal in 20% of patients with carpal tunnel syndrome, especially in mild and/or early disease. The above studies are also useful for assessing the severity of nerve compression, which can help in making therapeutic decisions about surgical intervention.

Many ultrasound studies have shown a significantly increased cross-sectional area of the median nerve at the carpal tunnel in patients compared with controls (figures 22A, B). However, the optimal cross-sectional area cut-off point for the diagnosis of median nerve entrapment has varied widely in these reports. Nevertheless, ultrasound can be useful in detecting local causes of median nerve compression at the carpal tunnel, such as ganglia, flexor tenosynovitis, wrist synovitis and muscle or bone abnormalities, which may change the approach to treatment. It has several advantages over MRI assessment, showing a higher spatial resolution, an ability to explore quickly long nerve segments accompanied by dynamic examination during muscle activity (Bruyn et al, 2012*).

Figure 22 (A) Transverse ultrasound image of median nerve (mn) enlargement in carpal tunnel syndrome. (B) Longitudinal ultrasound image of median nerve (mn) enlargement in carpal tunnel syndrome. C, capitate; ft, flexor tendons; l, lunate; r, radius.

A change of life and work style is mandatory for these patients. NSAIDs and night splints can be helpful in many cases. Although evidence for many conservative treatment options is scarce, local injection (preferably under ultrasound guidance) of glucocorticoid into the carpal tunnel is an effective therapeutic strategy. The presence of underlying causes (e.g., inflammatory arthritis, hypothyroidism) should be looked for. Where treatment is ineffective, patients may be suitable for carpal tunnel surgical decompression.

Carpal tunnel syndrome should be differentiated from the much less common entrapment of the median nerve where it passes through the pronator teres muscle in the proximal forearm (i.e., pronator teres syndrome) or other intrinsic nerve pathological conditions (e.g., schwannoma, figure 23). Patients present with forearm pain and sensory loss typically affecting the thenar eminence, which is usually not involved in carpal tunnel syndrome.

Figure 23 Schwannoma of the median nerve immediately proximal to the flexors retinaculum (outside the median nerve tunnel) is seen as a hypoechoic mass (between crosses). Preserved median nerve fascicular structure on the left side (arrow).

5.4 The hip

Accurate diagnosis of painful soft tissue disorders of the hip may be difficult in clinical practice. This section helps to clarify the frequent and unrecognised problem of non-traumatic lateral hip pain, the so-called greater trochanteric pain syndrome (GTPS) and describes the external and internal snapping hip that may cause lateral and medial hip pain.

5.4.1 Greater trochanteric pain syndrome

GTPS is a multifactorial syndrome characterised by dull aching lateral hip pain with a tender point(s) over the region of the greater trochanter. Although the cause of GTPS is not completely known, evidence suggests that it is associated with tendinopathy, from tendinosis to tendon tear, involving the gluteus medius and minimus with or without associated bursitis. Historically, GTPS has been named as hip periarthrititis, trochanteric bursitis or trochanteric tendinobursitis but these terms create confusion because bursal distension is an inconsistent feature of lateral hip pain. GTPS is usually diagnosed by clinical signs, with imaging techniques, conventional radiography, ultrasound or MRI useful for further elucidation.

5.4.1.1 Epidemiology and risk factors

The real prevalence of GTPS is unknown. It has been reported that GTPS is more prevalent in women than in men, and that unilateral GTPS is more common than bilateral GTPS. GTPS can be a comorbid condition in patients with altered lower limb biomechanics, obesity, low back pain or hip osteoarthritis (Segal et al, 2007).

5.4.1.2 Clinical anatomy

The gluteus medius and minimus are abductors of the hip joint. These muscles stabilise the hip joint, control pelvic rotation and ensure that the trunk maintains an upright position during the initial, mid- and late phase of the gait cycle. The outer and most superficial aspect of the greater trochanter is the insertion point of the tendons of the gluteus medius and minimus (figure 24). Three bursae have been consistently described surrounding the greater trochanter: sub gluteus minimus, sub gluteus medius and sub gluteus maximus bursae. The sub gluteus minimus is located next to the gluteus minimus tendon at the anterior facet medially to the anterior hip capsule. The sub gluteus medius bursa is located superior to the lateral facet. The sub gluteus maximus bursa is also known as the greater trochanteric bursae. The sub gluteus maximus bursa lies lateral to the greater trochanter, deep to the fascia lata and the gluteus maximus muscle.

5.4.1.3 Diagnosis

5.4.1.3.1 History

The patient is usually a middle-aged woman, with a history of frequent low back pain who has chronic, intermittent aching pain and tenderness in the lateral hip or buttock. The most common referral pattern extends from the lateral aspect of the thigh, rarely reaching the knee. Initially, the symptoms may be just a feeling of discomfort that insidiously increases or they can have a subacute onset. The patient's pain becomes worse when walking, climbing, running, sitting with the affected leg crossed, prolonged standing or switching to standing position. Occasionally, she/he refers to nocturnal pain that may be exacerbated by lying on the affected side. GTPS can be associated with variable degrees of disability.

5.4.1.3.2 Physical examination

The physical examination includes palpation and a provocative test. In patients with GTPS a painful area over the greater trochanter can be found.

Passive, active and resisted movements can reproduce the symptoms. The diagnosis is based on the presence of a history consistent with the complaint, and exclusion of an underlying alternative cause, such as spinally referred pain. Patients will often have gluteal weakness and a positive Trendelenburg test simply because they have gluteal weakness manoeuvres (Lequesne et al, 2008).

Hence, an extensive physical examination is essential in the differential diagnosis of GTPS (figure 25). The spine and peripheral neurology, and neural stretch tests must all be performed. As a general rule, the loss of flexion and extension movements of the hip owing to either pain or structural problems is characteristic of intra-articular problems of the joint. Depending on when and/or where the pain is reproduced, the Patrick-FABER (flexion, abduction, external rotation) test helps to diagnose iliopsoas tendinopathy and adductor muscle and tendon pathology. Ober's test is used to identify tensor fasciae or iliotibial band (ILT) contracture (i.e., patient lying on a table with the side to be tested up and the hip extended and abducted; attempting to adduct the leg towards the table, a positive test is found if the leg remains in the abducted position).

Figure 25 Palpating the trochanteric bursa (A) and muscle insertions in the vicinity (B). (Courtesy of Professor J A P Da Silva. Reproduced with permission from da Silva and Woolf. *Rheumatology In Practice*, Springer, 2010*.)

5.4.1.3.3 Imaging investigation

Radiography. Reactive sclerosis and bone proliferation can be seen in patients with gluteus tears. However, trochanteric spurs do not have clinical relevance at the site of a ligamentous or tendinous attachment. Bursal calcifications are often seen in the conventional radiographic examination of the elderly population.

MRI may be recommended in patients with a positive Trendelenburg's sign depicting a gluteus medius tear. The presence of peritrochanteric oedema seems to be associated with GTPS. The presence of bursitis on MRI has been reported in a variable number of patients independently of the presence of GTPS.

Ultrasound serves to identify bursae, trochanteric facets and the corresponding tendinous and muscular attachments of the gluteus. Ultrasound allows us to depict the direct and indirect signs of tendinopathy, ranging from tendinosis to partial or full thickness tear, and enthesopathy and corresponds well to MRI and surgical pathological findings in GTPS. The signs of gluteus tendinopathy include thickening of the tendon, hypoechogenicity and loss of the homogeneity of the tendon fibres in comparison with the contralateral side. In the case of a partial thickness tear, partial discontinuity of the gluteus minimus or medius is seen (figures 26 and 27). When there is a full thickness tear of the gluteus medius at the lateral facet insertion, ultrasound shows a complete absence of the tendon, creating an image of the 'bald trochanter' with direct contact between the fascia lata and the lateral facet of the greater trochanter. Indirect signs of rupture are represented by irregularity of the cortical bony surface or the presence of bursitis (Klauser et al, 2013*).

Figure 26 Longitudinal ultrasound image of the gluteus minimus. AF, anterior facet of the greater trochanter; FL, fascia lata; Gm, gluteus minimus.

Figure 27 Longitudinal ultrasound image of partial tear of the gluteus medius. GM, gluteus medius; PSF, superoposterior facet of the greater trochanter; ***, loss of convexity of the gluteus medius tendon owing to partial tear.

5.4.1.4 Management

Few controlled studies have tested the efficacy of the different strategies for treatment of GTPS. Conservative treatment includes behaviour modification, weight loss in obese patients and the use of NSAIDs or analgesics according to need, physical therapy.

Guided injection of local glucocorticoid and anaesthetic at the point of maximal tenderness or slightly more posteriorly can provide a short to mid-term beneficial effect for pain relief. Variable rates of response have been described, (Labrosse JM et al, 2010), video 6. Hence injection is optimally reserved for those cases where bursitis is present rather than solely for tendinopathy. Some patients may have relapse within the next few months, especially those with severe degenerative disease. Most patients respond to non-surgical management but in patients refractory to treatment, arthroscopic bursectomy, ILT lengthening,

decompression of the peritrochanteric space and, if the gluteus tears, suture anchor tendon repair to the greater trochanter have been used. These interventions should be considered only rarely.

Video 6. Real time video for corticosteroid injection inside the trochanteric bursitis. Transverse scanning at the level of the greater trochanter. Hypoechoic material is distending the bursa. The needle is penetrating 'in plane' and drug deposition (hyperechoic substance distending the bursa) is made strictly inside the trochanteric bursa. (You must be connected to internet and use Acrobat reader to see the video. Another version is available in the "images" section of the course)

5.4.2 Coxa saltans (snapping hip)

Coxa saltans is a clinical condition with multiple causes. It is characterised by a painful, audible snap when the hip is flexed and extended. Snapping hip commonly occurs in young adults, who report mechanical symptoms such as clicking, popping or catching in activities involving hip flexion such as dancing, running, gymnastics or soccer. Depending on the location of the snapping it can be classified as external and internal.

The external coxa saltans is the most common snapping hip. An abnormally thickened area of the posterior border of the ILT, tensor fascia lata muscle, gluteus medius tendon or the leading anterior edge of the gluteus maximus snaps back and forth over the greater trochanter. The syndrome can be reproduced during flexion, extension, adduction or internal rotation of the hip. Clicking appears more often when hip moves from flexion to extension. The underlying bursa may become inflamed. This syndrome may be associated with leg length discrepancy, weakness in hip abductors and external rotators, tautness in the ILT, lumbopelvic instability and excessive pronation of the foot.

The internal coxa saltans can be produced by either extra-articular or intra-articular causes, which have similar mechanisms. The musculotendinous iliopsoas snaps over the femoral head, the anterior capsule of the hip, the lesser trochanter or the iliopectineal ridge with extension of the hip from a flexed position. Enlarged iliopsoas bursa can be seen. Intra-articular snapping is due to lesions in the joint itself.

Diagnosis of coxa saltans is usually based on medical history and clinical examination. Dynamic ultrasound studies help to clarify the different causes of extra-articular snapping hip. The main principle of management is conservative treatment. When needed, glucocorticoid injections and the use of ultrasound to guide the needle in barely accessible structures, such as the iliopsoas bursa, improve the patient's symptoms. Surgery is required only occasionally in recalcitrant cases.

5.5 The knee

To determine the origin of pain in soft tissue around the knee is a challenge because of extensive differential diagnoses. The patient's age, medical history and physical examination specifying the anatomical site of the pain are fundamental to achieving an accurate diagnosis. Knee soft tissue pathologies are common in sports and often appear in those with little training. This section aims to review the most common soft tissue pathologies of the knee. Pathologies of the quadriceps and patellar tendon are grouped for a didactic purpose under the concept of extensor knee mechanism pathology.

5.5.1 The iliotibial band syndrome

The iliotibial band syndrome (ILTS) consists of pain and tenderness over the lateral femoral condyle during movements of flexion and extension of the knee.

The ILT has two distal insertions in the knee joint. Proximally, it is inserted, into the lateral epicondyle of the femur with a broad expansion between the lateral aspect of the patella, whereas distally it is inserted into Gerdy's tubercle. The ILT is an anterolateral knee stabiliser. (figure 28). An 'impingement zone' has been described when at 30° of knee flexion the ILT passes over, and posterior to, the lateral femoral epicondyle.

Figure 28 Anatomical image of the iliotibial band. ITB, iliotibial band; LR, lateral retinaculum; PT, patellar tendon. (Image provided as a courtesy of Professor Maribel Miguel, Human Anatomy and Embryology Unit, Department of Pathology and Experimental Therapy, Faculty of Medicine (Bellvitge), University of Barcelona, Spain.)

The cause of ILTS is multifactorial and diverse. Several anthropometric variables have been implicated, including excess internal tibial rotation, genu varum, over pronation of the foot or leg length inequality. Extrinsic factors such as improper footwear, running, bicycle fit or saddle position and training errors may overstress the ILT and cause ILTS. Comorbid conditions such as knee or hip osteoarthritis may also influence the appearance of ILTS. It is a common overuse running injury.

To assess ILTS, clinicians obtain a medical history and carry out a physical examination. Complementary ultrasound can show changes in the ILT echo texture or associated bursitis.

Modification of activity and training habits, stretching of the ILT and strengthening of the gluteus medius and major muscle have been proposed as treatment of the ILTS. A systematic review of prospective RCTs for conservative management of ILTS showed limited evidence for the usefulness of the interventions examined, including NSAIDs, deep friction massage, phonophoresis versus immobilisation and local glucocorticoid injection. Surgery has been advocated for patients refractory to conservative treatment (van der Worp et al, 2012).

5.5.2 Disorders of the extensor mechanism of the knee

The extensor mechanism of the knee includes the quadriceps muscle and tendon, the patella, the patellar retinaculum, the patellar tendon, the fat pads (suprapatellar, prefemoral, infrapatellar or Hoffa's) and the bursae (suprapatellar, pretibial and prepatellar). It constitutes a functional complex that allows extension of the knee joint. The pathology of the patella is included in this section, although obviously related to failure of the extensor mechanism. The quadriceps tendon inserts into the tubercle of the tibia through the retinaculum of the patella, and the patellar tendon then joins with the fascia of the leg as do other muscles in the lower extremity, such as the semimembranosus, semitendinosus gracilis and sartorius (figure 29). These muscles end in tendons and also in fascial expansions to accomplish their function of stabilising the leg.

Figure 29 Anatomical image of the medial knee. G, gracilis; GM, medial gastrocnemius; MR, medial retinaculum; P, patella; PA, pes anserinus; QT, quadriceps tendon; S, sartorius; SM, semimembranosus; ST, semitendinosus. (Image provided as a courtesy of the Faculty of Medicine (Bellvitge), University of Barcelona, Spain.)

As an example, jumper's knee classically refers to an insertional tendinopathy of the posterior aspect of the patellar tendon at the enthesis into the inferior patellar pole; but jumping pathology may also include tendinopathy of the insertion of the patellar tendon into the tibial tuberosity, or tendinopathy of the attachment of the quadriceps tendon, because all these tendons and others are involved in jumping. Acute trauma, overuse injuries and chronic degenerative diseases are the most common pathology found in the extensor mechanism, ranging from minimal damage to complete tendon tears.

5.5.2.1 Jumper's knee

Jumper's knee is seen in young athletes as a result of repetitive microtraumas and can be considered a predisposing factor for patellar tendon rupture.

5.5.2.2 Patellar tendon rupture

Patellar tendon rupture may also occur as a consequence of degenerative tendon or systemic diseases, with local or systemic glucocorticoid injections being a controversial predisposing condition. The rupture can be partial or complete and localised either at the proximal or distal enthesis or at the mid-point. The most common site is at the osteotendinous junction of the tendon with the lower pole of the patella.

When patellar tendinopathy is suspected, in addition to a history of patellar pain, tenderness to palpation has been shown to be a reliable test without correlation with either imaging or evolution of symptoms. When complete rupture of the patellar tendon has occurred, physical examination shows the presence of a palpable gap inferior to the patella, high-riding patella or 'patella alta', weakness on the knee joint extension and inability to walk.

Imaging is recommended to confirm the diagnosis. Ultrasound evaluation of the patellar tendon can ascertain the presence and location of either degenerative changes and a partial or complete tear, although the correlation between these findings and the symptoms is not clear. A Doppler signal can show evidence of neovascularisation in a variable percentage of patients with vessels entering into the tendon from the dorsal side. The presence of a Doppler signal in patients with chronic disease tends to be associated with lower functional scores and more pain (Hoksrud et al, 2008) (figure 30).

In complete tendon tear the radiographic presence of 'patella alta' in a lateral view of the knee in slight flexion with infrapatellar soft tissue swelling confirms the physical assessment.

Management. Controlled loading of the tendon—for example, by an eccentric decline squat regimen, is the central component of treatment. Controlling pain through analgesics, massage, ESWT and biomechanical alterations should also be considered. Glucocorticoid injections are contraindicated and evidence for other

injection therapies is not strong. Surgical repair is the most common treatment for complete patellar tendon rupture with different techniques described in the literature.

Figure 30 Proximal patellar tendinopathy. The ultrasound image shows hypoechoic thickening of the proximal aspect of the patellar tendon (arrow).

5.5.2.3 Quadriceps tendinopathy

Quadriceps tendinopathy is less common than patellar tendinopathy and can be seen in older patients, who usually have an underlying systemic disease. Tears often occur in a weakened degenerative tendon during eccentric contraction, since as the muscle lengthens so to do the higher forces needed. Clinical history and physical examination shows pain and limitation or the impossibility of actively extending the knee, whereas active flexion remains preserved; when the retinaculum is intact, the patient can extend the knee. Therefore, it is necessary to compare the damaged extremity with the opposite leg. If the classic sign of a suprapatellar gap is masked owing to the presence of swelling, active flexion of the hip improves visualisation of the tendon defect. The patient may be able to move about.

The most common abnormalities seen on radiography are inferiorly displaced patella, suprapatellar mass due to retraction of the ruptured tendon, calcifications and alteration of the tendon shadow.

In addition to the high degree of sensitivity and specificity shown by ultrasound in assessing complete tendon tears, dynamic ultrasound shows the tendon gap and can be used to follow up the postoperative repaired tendon. The treatment combines local measures, immobilisation, exercise and knee aspiration to evacuate the traumatic haemarthrosis, if needed. Early surgical repair is suggested in acute complete rupture to achieve good functional outcome; in cases of chronic complete rupture, the surgical results are less satisfactory.

5.5.2.4 Pes anserinus bursitis

The pes anserinus refers to the conjoined tendons of the sartorius, gracilis and semitendinosus at their insertion into the proximal tibia. The tendons run superficial to the medial collateral ligament. A bursa located

distal and anterior to the medial collateral ligament bursa can be irritated and inflamed with repetitive microtrauma. The underlying factors of this condition include factors such as valgus stress, osteophytes, exostoses, tendon tightness, obesity and diabetes. The pain can be located or vague around the medial aspect of the knee (figure 31), being more intense while ascending or descending stairs.

Figure 31 Area of tenderness associated with *pes anserinus tendinopathy* (right knee, medial aspect). (Courtesy of Professor J A P Da Silva. Reproduced with permission from da Silva and Woolf. *Rheumatology In Practice*, Springer, 2010*.)

Ultrasound (figures 32A–C) can identify pes anserinus bursitis in its location. The treatment includes stretching of the adductor and quadriceps muscles and/or local injection if the pain is persistent.

5.6 The foot and ankle

The hand and foot are different structures having different functions—an obvious statement coming from Wood Jones, but fundamental to understanding foot pathology. The foot has been designed for support and locomotion. For these reasons the muscles of the leg and foot have wide and powerful insertions through fascias to large areas favouring the increase of its strength and stability. The calcaneal or Achilles tendon is the largest and strongest tendon in the human body. It is formed as the conjoined tendon of the gastrocnemius and soleus, with its fibres arranged in a spiral form being more superficial than those provided by the tibial side of the muscle. Some of the superficial fibres of the Achilles tendon become continuous with the plantar aponeurosis or plantar fascia (figures 33 and 34).

Figure 32 (A) *Pes anserinus*. Longitudinal image of the medial collateral ligament insertion. 1, medial collateral ligament; 2, sartorius; 3, tibial bone; 4, inferior medial geniculate vessels; 5, soft tissue. 5.6.1 Achilles tendon disorders

As a consequence of its large size and immense functional demands, the Achilles tendon is susceptible to a wide spectrum of acute and chronic injury along its entire length, which will be considered in this section.

5.6.1.1 Paratenonitis, tendinosis and enthesopathy

Most cases of Achilles paratendonitis and tendinosis are related to overuse, although there are some exceptions. Although 25–33% of patients are reported to be not actively involved in sport, occupational activities may be implicated in their development. In runners, 55–65% of lesions are peritendinous and 20–25% are insertional. The vast majority (80%) of people affected are men. There are no reports of the relative risk in different sports and there seems to be significant variation between countries.

A number of aetiological factors have been implicated in the development of Achilles tendon lesions, particularly being overweight, repetitive impact loading, biomechanical factors (hyperpronation and leg length inequality) and/or sudden acceleration (ruptures). Oral fluoroquinolones are well recognised as a cause of Achilles tendinopathy and cause a florid inflammatory response. Risk factors include male gender, and the use of systemic glucocorticoid therapy, renal failure, advanced age and hypercholesterolaemia.

For example, both heterozygous familial type II hyperlipidaemia (where there is an increased total and low-density lipoprotein cholesterol value of two to three times normal) and mixed hypercholesterolaemia (increased cholesterol and triglycerides) are associated with tendon xanthomas and Achilles tendinopathy. Indeed, the musculoskeletal complaints may be the presenting features of these disorders. Lipid storage diseases such as cerebrotendinous xanthomatosis are also associated with Achilles tendinopathy.

5.6.1.2 Haglund's syndrome

This is a syndrome of an exostosis of the posterosuperior calcaneum in association with a retrocalcaneal bursitis and Achilles insertional tendinopathy.

5.6.1.3 Ruptures

Rupture of the Achilles tendon is the most common form of spontaneous tendon rupture, affecting men more often than women. Ninety per cent of ruptures occur owing to physical activity. Only 10% of all those who rupture have had previous Achilles tendon symptoms, 30% of whom are only mildly symptomatic. Rupture usually occurs 3–6 cm above the insertion (83%), while 12% occur at the musculotendinous junction and 5% at the insertion (Hattrup and Johnson, 1985). Simultaneous bilateral rupture is rare but successive ruptures are relatively more common. Iatrogenic causes of Achilles tendon rupture must also be considered, including fluoroquinolones and glucocorticoid injections.

5.6.1.4 Diagnosis of Achilles tendon disorders

5.6.1.4.1 History

Symptoms may vary from pain, stiffness and severe inflammation to a minor ache, depending upon the specific disorder. Pain may be worst at the beginning of the day, with start-up pain (difficulty in putting the foot to the floor on getting out of bed). Precipitating factors must be sought, including activities, types of footwear and trauma. In the sporting population a careful history must be taken of training patterns, surfaces, equipment use (including shoes), previous injuries and additional training activities. In acute spontaneous ruptures the history of a loud bang and a feeling as if the patient has been kicked in the back of the leg, with subsequent difficulty in pushing off, is virtually diagnostic. However, pain may be absent and symptoms vague. Partial tears of the Achilles tendon may occur as a result of a distinct episode or a series of pain episodes. In individuals with insertional tendinopathies, a systemic enquiry into the possibility of an associated spondyloarthritis is important (box 9).

Box 9 Enthesopathies: associated spondyloarthritides

- Psoriatic arthritis
- Reiter's syndrome/reactive arthropathy
- Enteropathic arthritis (Crohn's disease, ulcerative colitis)
- Ankylosing spondylitis
- Seronegative enthesopathic arthropathy syndrome
- Undifferentiated spondylitis

5.6.1.4.2 Physical examination

Paratenonitis, tendinosis and tears most commonly occur in the mid-third section of the tendon, where the area is relatively hypovascular. Local tenderness, inflammatory signs and/or a palpable tendon nodule may be evident (figure 35).

Figure 35 Palpation of the Achilles tendon and pre-Achilles bursa. (Courtesy of Professor J A P Da Silva. Reproduced with permission from Da Silva and Woolf, *Rheumatology In Practice*, Springer, 2010*.)

Stiffness of the gastrocnemius–soleus complex is common. The tendon may be swollen and generally tender with crepitus in acute paratenonitis. In acute ruptures, swelling and bruising may be evident and in the chronic ruptures, local thickening of the tendon and peritendinous tissues and muscle atrophy are commonly seen. Achilles tendon rupture can be detected by the angle at which the feet dangle over the end of the examining couch (figure 36). Rupture is confirmed by absence of plantar flexion of the foot when the examiner squeezes the calf. The patient is unable to perform a single heel raise and a palpable gap may be present.

Partial tears are often difficult to diagnose; weakness of dorsiflexion and a failure to respond to conservative management should arouse suspicion but imaging is usually necessary.

Insertional tendinopathy (i.e., enthesopathy) is commonly associated with a retrocalcaneal bursitis and a Haglund's deformity (also called 'pump bump'), particularly in association with a hypermobile rear foot. Insertional tendinitis causes local tenderness, swelling and hyperaemia at the insertion.

Figure 36 Achilles tendon rupture—loss of plantar flexion (right). (Reproduced with permission © Royal College of Surgeons in Ireland Illustrations.)

In retrocalcaneal bursitis, bursal swelling is often seen on both sides of the Achilles tendon, although it is not so obvious in chronic situations. In acute and subacute cases, there is painful swelling and occasionally hyperaemia of the overlying skin in the posterosuperior corner of the calcaneus. Dorsiflexion of the foot is painful.

Predisposing anatomical factors should be sought. Gait should be assessed for hyperpronation, leg length discrepancy and deformities.

5.6.1.4.3 Imaging of Achilles tendinopathies

Ultrasound should be performed as an extension of the clinical examination. Abnormal findings can be identified at the paratenon, the tendon echo texture and the enthesis. Ultrasound imaging helps to distinguish full thickness tears from other Achilles tendinopathies.

Retrocalcaneal and retro Achilles bursae can also be detected using ultrasound (figures 37A, B). MRI is particularly useful in evaluating the surrounding bony abnormalities and retrocalcaneal pathologies.

Radiography may be helpful in the assessment of a Haglund's deformity, or bony spurs associated with insertional tendon pain.

Figure 37 (A) Longitudinal ultrasound image of retrocalcaneal bursitis (b). (B) Longitudinal ultrasound image of the Achilles tendon presenting increased thickness, a loss of the normal fibrillar structure and positive Doppler sign. The retrocalcaneal bursa (B) is occupied by an inhomogeneous hypoechoic mass. A, Achilles tendon; AT, Achille's tendon; C, calcaneum.

5.6.1.4.4 Management of Achilles tendinopathies

Paratenonitis and tendinosis. The focus, as in all core tendon injuries, is controlled loading. As is the case with so many soft tissue injuries, controlling symptoms to allow rehabilitation is a central goal. In acute and subacute cases, the Protect, Rest, Ice, Compression, Elevation, Support (PRICES) approach is appropriate. Rest is relative; reducing the intensity, frequency and duration of loading activities and cross-training through the adoption of alternative modes of activity that do not stress the tendon (swimming, cycling) is encouraged. In cases of severe inflammatory enthesopathies, in particular, functional casting or, rarely, the use of crutches, may be necessary. Cryotherapy in the form of ice, cold compresses or ice immersion is used to control pain, reduce muscle spasm, oedema, regional blood flow and the metabolic demands of tissue, and thereby prevent further tissue damage.

Topical NSAIDs can help; high drug levels in the tendon can be achieved with a low risk of side effects, local massage of the drug into the tendon itself can provide relief.

Once the very acute symptoms have resolved, early stretching of the gastrocnemius and soleus muscles separately, in addition to hamstring stretching, is important. Heat may be useful later in providing analgesia, reducing muscle spasm, improving tissue extensibility, inducing vasodilatation, and increasing vascular permeability and metabolism. Warm whirlpools, warm packs, hot gels, contrast baths, paraffin wax and infrared may all be used for this purpose.

Local modalities, including ultrasound, deep heat and laser, may be useful but evidence for their effectiveness is limited, and they should not divert attention away from rehabilitation. The use of a dorsiflexion night splint or other orthotics should be considered and gradual strength training of the lower leg musculature should be introduced once the patient is pain free.

Attention to precipitating factors is important, such as exercise concerns or biomechanical factors (e.g., walking patterns, shoe wear).

Where implicated, fluoroquinolones must be withdrawn immediately and treatment of the local disorder is necessary. Where the tendinosis is associated with hyperlipidaemic states, treatment with a statin is indicated.

Appropriate rehabilitation is essential for a successful return to full activities. This includes stretching of the gastrocnemius–soleus complex and hamstrings and gradual strengthening of the calf musculature, the fundamental component being an eccentric muscle training programme, or a similar loading regimen.

Glucocorticoid injections have no role to play, as they are usually ineffective and may weaken the tendon, with resulting rupture.

Although most cases are managed conservatively, surgery may be considered in those people whose movement remains significantly limited despite intensive rehabilitation for 12–18 months. Numerous surgical techniques, alone or in combination, have been advocated, although none have been rigorously evaluated. Surgery in this area may result in significant complications, including poor wound healing, local nerve damage, infection and failure of the repair.

Enthesopathy and bursitis. Treatments are similar to those described above. Relief of friction between the heel counter of footwear and the bursal projection by padding and modification of the shape, height and rigidity of the heel counter are all recommended. ESWT can be useful in cases of calcific disorders or ossification of the Achilles tendon, which most commonly occurs at the insertion.

In acute bursitis with intrabursal fluid, aspiration and glucocorticoid injection can be performed. Haglund's syndrome may take many months to show signs of improvement with conservative measures.

Patients with recalcitrant retrocalcaneal bursitis or Haglund's syndrome may be managed surgically. This may involve debridement or resection of the bursa, or (as appropriate) excision of the posterior superior calcaneus (Haglund's deformity). Calcaneal osteotomy has also been advocated, although this is considerably more invasive.

A seronegative arthritis should be considered in those patients who have persisting insertional Achilles tendinopathy and/or retrocalcaneal bursitis. Ultrasound with a Doppler technique has shown promising results as a diagnostic tool for distinguishing between degenerative and inflammatory (i.e., spondyloarthritis) enthesal involvement.

Rupture. Initial treatment of the acute Achilles tendon rupture requires the PRICES regimen. The options are then early surgical repair and 6 weeks bracing, or bracing for 8 weeks. Re-rupture rate is similar for both approaches but is variably reported to be 0–50%. However, non-surgical management is also acceptable,

particularly for a patient who is less active or not a good candidate for surgery. An aggressive postoperative regimen is commonly followed, with early mobilisation and the start of rehabilitation.

Partial tears. Partial Achilles tears are often classified as tendinosis and are managed in the same way. In the acute stage, management follows the PRICES regimen for 4–7 days, with rest to prevent further tear and the use of a brace support. Surgery is rarely necessary but can be used for those who do not respond to conservative treatment, or for those with substantial tears.

5.6.2 Plantar fasciitis

Plantar fasciitis comprises inflammation of the insertion of the plantar fascia on the medial process of the calcaneal tuberosity (figure 38).

Figure 38 *Palpation of the posterior insertion of the plantar fascia. (Courtesy of Professor J A P Da Silva. Reproduced with permission from da Silva and Woolf. Rheumatology In Practice, Springer, 2010*.)*

The aetiology is multifactorial but most of the cases are linked to overuse stresses. Possible risk factors include prolonged standing and weight bearing, obesity and heel spurs. Excessive stretching of the plantar fascia can result in repetitive microtrauma of this structure and produce chronic degeneration/rupture of the fascial fibres.

Pain is experienced on the plantar surface of the foot, especially with the first steps after periods of inactivity.

Ultrasonography identifies an increase in the thickness of the fascia, hypoechogenicity and oedema at the level of the calcaneus insertion, as well as loss of definition between the fascia and the surrounding soft tissue (figure 39A). MRI and radiography are useful when other pathologies are suspected.

Figure 39 (A) Longitudinal scanning of the plantar fascia (PF), which has increased thickness and a convex shape (arrows). (B) Longitudinal scanning of the plantar fascia (PF). Glucocorticoid deposition (hyperechoic line, arrow) at the interface between the PF and subcutaneous tissue.

The treatment includes rest and activity changes, ice, NSAIDs, local glucocorticoids (figure 39B), splinting, shoe modifications and orthoses. Some physical therapy programmes, such as stretching, ultrasonography and iontophoresis, may be used as adjuncts.

In refractory cases, apart from surgical procedures, other treatment techniques like PRP injection, glyceryl trinitrate patches and ESWT, have been used.

SUMMARY POINTS

- Soft tissues, including tendon, muscle, bursa, ligament and fascia, are the most common source of pain presenting to rheumatologists.
- Soft tissue complaints can be due to localised pathology, or related to systemic disease, such as inflammatory arthritides, diabetes, hormonal causes and drugs.
- Establishing a specific diagnosis in a patient with a soft tissue disorder is vital to guide best management.
- The assessment of soft tissue lesions involves taking a careful history and performing a thorough clinical examination, based upon 'Look, Feel, Move, Special Tests'.
- Imaging, particularly diagnostic ultrasound and magnetic resonance imaging, provide information on structural changes in tissues and surrounding anatomy, but should be used only in the context of the clinical picture.
- Musculoskeletal ultrasound is a bedside imaging modality that provides accurate soft tissue diagnoses and guidance for therapeutic injections.
- Rotator cuff disorders are the most common causes of shoulder pain in adults.
- Sepsis and gout should be considered in any patient presenting with an acute red hot bursitis.
- Management of many soft tissue complaints, and in particular those affecting a tendon, involves focused exercise-orientated rehabilitation, facilitated by good management of pain.
- Glucocorticoid injections are often used for soft tissue complaints, but should be reserved for recalcitrant conditions where pain or inflammation is limiting rehabilitation.

IN-DEPTH DISCUSSION I

**Wrist pain related with ligamentous structures:
Scapholunate ligament pathology**

1.a Introduction

The rheumatologist often cares for patients with dorsal wrist pain or discomfort which is not always inflammatory in nature. The following discussion considers one possible cause: the Scapholunate ligament (SLL) and its pathology.

The wrist is formed by two rows of carpal bones, proximal and distal, joined by a system of intrinsic and extrinsic ligaments enabling the proximal carpal row to act as the link between the static components of the forearm and the distal carpal row. The ranges of motion of the carpal joints are complex and dependent on the integrity of these ligamentous structures. The SLL is one of the most clinically important ligaments of the wrist. SLL clinically relevant anatomy, diagnostic evaluation and treatment will be discussed.

1.b Anatomical details relevant for the diagnostic and treatment.

The SLL is an intrinsic ligament in the proximal row of the carpal bones. The SLL consists of volar (palmar), dorsal and interosseous components. The volar component contributes to rotational motion of the wrist and is highly innervated, thus having a proprioceptive role as well. It is in continuity with the extrinsic volar radioscapholunate ligament. The intermediate component of the SLL is primarily fibrocartilaginous tissue with minimal blood supply which makes it susceptible to the development of degenerative tears or crystal deposition. The dorsal component contributes in the control of the flexion and extension of the wrist joint and is the key component in maintaining the relationship between scaphoid and lunate; the edges blend with the radiocarpal joint capsule and the scaphotriquetral and dorsal intercarpal ligaments. The dorsal SLL is subjected to very strong forces owing to wrist architecture where the scaphoid bone is the link between the proximal and distal row of carpal bones and the movements of radial- ulnar deviation. Flexion and extension occur about the lunate bone. In addition to the SLL, the scapholunate joint also has secondary static stabilizers responsible at the extremes of motion such as the scaphotrapezial-trapezoidal and the radioscaphocapitate ligaments and dynamic stabilizers including the flexor carpi radialis tendon (FCR). The FCR is important during the wrist movements by providing dynamic stabilization of the scaphoid by utilizing its insertion into the scaphoid tuberosity which then extends to its final insertion at the second metacarpal bone. Salva Coll et al (2011) showed that the FCR has capability to extend and supinate the scaphoid and pronate the triquetrum resulting in scapholunate joint junction and dorsal SLL relaxation. This is the basis for the positive effect of FCR re-education in dynamic scapholunate instabilities. Anatomical risk factors for SLL damage are an ulna minus configuration, lunotriquetral coalition and the slope of the radial articular surface.

1.c Diagnostic evaluation

SLL damage commonly results from severe injury or low-grade repetitive trauma. Patients with CPPD deposition disease can have calcium pyrophosphate dehydrate crystal deposition in the fibro-cartilaginous intermediate portion of the ligament with subsequent damage of the SLL. Injuries in the dorsal portion of SLL are related with symptoms whereas tears of the fibro-cartilaginous portion are mostly asymptomatic. Injuries of the volar component are potentially associated with damage to the volar radioscapholunate ligament. These patients present with tenderness located in the region of the scaphoid and lunate bones at the radial side of the wrist. They may experience a painful clicking with decreased grip strength. This may be the result of severe direct trauma or repetitive low-grade trauma with the wrist in hyperextension. A tender point may be noted at the proximal end of the snuffbox just distal to the Listers's tubercle.
